Essential reference works for every life sciences' library

FASEB'S BIOLOGICAL HANDBOOKS

CELL BIOLOGY (1976)

454 pages, 102 tables

I. General Cell Characteristics
II. Cell Environment
III. Cell Periphery
IV. Mitochondria
V. Endoplasmic Reticulum, Microsomes, Ribosomes, and Golgi
VI. Lysosomes, Peroxisomes, Granules, and Microbodies
VII. Nuclei

ISBN: 0-913822-10-8 $45.00

"Until now, biology has lacked its "Beilstein" and it is often a time-consuming business to find some small piece of factual information which you know has been published. This book compresses the maximum amount of information into the minimal space and at the same time gives key references from which a quick general overview of the field of interest may be made…the amount of information available is remarkable." *Nature*

BIOLOGY DATA BOOK, Second Edition

Volume I (1972)
606 pages, 71 tables

I. Genetics and Cytology
II. Reproduction
III. Development and Growth
IV. Properties of Biological Substances
V. Materials and Methods

ISBN: 0-913822-06-X $40.00

RP391

Volume II (1973)
826 pages, 96 tables

VI. Biological Regulators and Toxins
VII. Environment and Survival
VIII. Parasitism
IX. Sensory and Neuro-Biology

ISBN: 0-913822-07-8 $40.00

Volume III (1974)
691 pages, 114 tables

X. Nutrition, Digestion, and Excretion
XI. Metabolism
XII. Respiration and Circulation
XIII. Blood and Other Body Fluids

ISBN: 0-913822-08-6 $40.00

Three Volume Set of Biology Data Books:
ISBN: 0-913822-09-4 $100.00

"No review can adequately cover the extent of these data books. Innumerable contributors and reviewers have played a part and the result is a collection of information of the highest order. No library serving industry or the universities and colleges where biological sciences are an integral part of their activities can afford not to have these volumes." *Chemistry and Industry*

RESPIRATION AND CIRCULATION (1971)

930 pages, 232 tables

I. General Principles
II. Basic Physical and Chemical Data
III. Thorax and Ventilation
IV. Airways and Gas Movement
V. Blood Gases
VI. Heart and Pumping Action
VII. Vascular System and Blood Distribution
VIII. Capillaries and the Exchange System
IX. Invertebrate Respiration
X. Invertebrate Circulation
XI. Plant Respiration and Fluid Movement

ISBN: 0-913822-05-1 $30.00

"This type of compilation has a major place in scientific information retrieval, and the editors and contributors are to be complimented on their achievement and thanked for their assistance to the greater body of investigators and teachers who will find the volume useful." *Gastroenterology*

ENVIRONMENTAL BIOLOGY (1966)

694 pages, 190 tables

I. Temperature
II. Radiant Energy
III. Sound, Vibration, and Impact
IV. Acceleration and Gravity
V. Atmosphere and Pollutants
VI. Atmospheric Pressures
VII. Gases
VIII. Water
IX. Solutes
X. Biological Rhythms

ISBN: 0-913822-03-5 $15.00

"The editors have done an admirable job in organizing the data from approximately 450 contributors. Data are presented in 190 tables with the contributors and references listed immediately following each table. Hence, the handbook can serve as a convenient reference source for select environmental factors." *Environmental Science and Technology*

All prices are postpaid to any part of the world.

Guide to authors

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:
(i) only one reference number need be used if the reference is to several papers by identical authors,
(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use of the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258,** 1 (1975) and **264,** v (1976).

Frog retinal ganglion cells show species differences in their optimal stimulus sizes	*R. D. Glickman and B. Pomeranz*	51
Normal postimplantation development of mouse parthenogenetic embryos to the forelimb bud stage	*M. H. Kaufman, S. C. Barton and M. A. H. Surani*	53
Antigenic deletion and malignant enhancement induced in lymphoma cells by passage through X-irradiated hosts	*H. L. Ioachim, A. Pearse and S. E. Keller*	55
Suppressor T-cell inactivation of a helper T-cell factor	*L. Harwell, P. Marrack and J. W. Kappler*	57
Androgen-modified expression compared with Y linkage of male specific antigen	*R. P. Erickson*	59
Specific binding of a synthetic oligodeoxyribonucleotide to yeast cytochrome *c* mRNA	*J. W. Szostak, J. I. Stiles, C. P. Bahl and R. Wu*	61
Anomaly in the γ chain heterogeneity of the newborn	*T. H. J. Huisman, W. A. Schroeder, A. Felice, D. Powards and B. Ringelhann*	63
Evidence for localisation of genes for human α-globin on the long arm of chromosome 4	*E. Gandini, B. Dallapiccola, L. Colette, E. F. Suerinc, A. Forabosco, F. Conconi, and L. Del Senno*	65
Vitamin A receptors in normal and dystrophic human retina	*D. R. Bergsma, B. N. Wiggert, M. Funahashi, T. Kuwabara and G. J. Chader*	66
Identification of a membrane protein binding the retinol in retinal pigment epithelium	*G. Maraini, S. Ottonello, F. Gozzoli and A. Merli*	68
Specific binding sites for oestrogen at the outer surfaces of isolated endometrial cells	*R. J. Pietras and C. M. Szego*	69
Abnormal myelination in transplanted Trembler mouse Schwann cells	*A. J. Aguayo, M. Attiwell, J. Trecarten, S. Perkins, and G. M. Bray*	73
Spontaneous and evoked potentials from dissociated epithelial cells of *Hydra*	*G. Kass-Simon and V. K. Diesl*	75
Response of cricothyroid muscles to frequency-modulated sounds in FM bats, *Myotis lucifugus*	*P. H.-S. Jen and J. Ostwald*	77
Suppression of noradrenaline synthesis in sympathetic nerves by carbidopa, and inhibitor of peripheral dopa decarboxylase	*R. J. Wurtman and C. J. Watkins*	79
Dopamine is a monoamine oxidase B substrate in man	*V. Glover, M. Sandler, F. Owen and G. J. Riley*	80
Concanavalin A as a carrier of daunomycin	*T. Kitao and K. Hattori*	81
Recognition sequence of specific endonuclease *Bam*HI from *Bacillus amyloliquefaciens* H	*R. J. Roberts, G. A. Wilson and F. E. Young*	82
Relationship of spasmogenic and smooth muscle relaxant peptides from normal lung to other vasoactive compounds	*S. I. Said and V. Mutt*	84

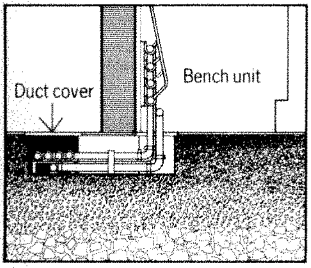
The ins and outs of good laboratory design

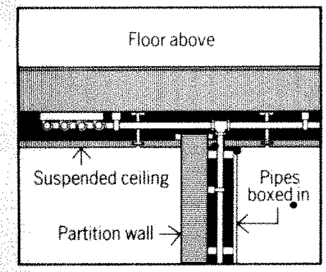
The ins

Services

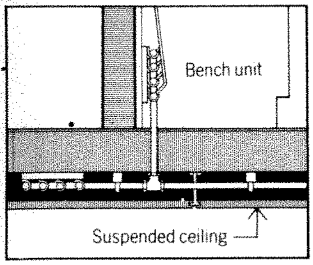
In a multi-storey building, main service feed pipes should be installed in clear vertical ducts and then distributed laterally, either wall mounted to serve ring mains or wall benches or in one of these three other ways:



Pipes in floor trench.
(Ground floor only)



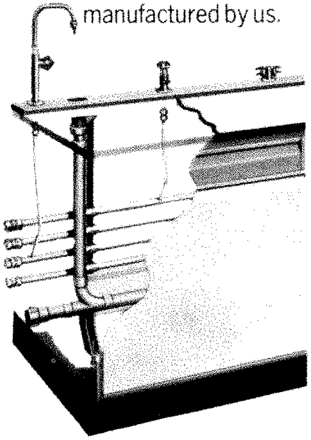
Pipes suspended from ceiling and dropping to individual benches.



Pipes on ceiling of floor below and rising through floor slab to feed benches above.

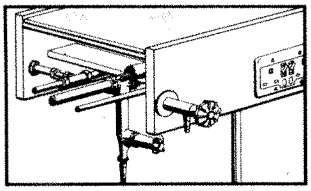
Pipework Systems

Unless service pipework is pre-planned, it can often mean unnecessary expense and time wasted in installation. Morgan and Grundy plan the pipework from precise pick-up points, using either the traditional method of clipping pipework to the wall or the backs of furniture units or prefabricated pipework support racks designed and manufactured by us.



Service Ducts

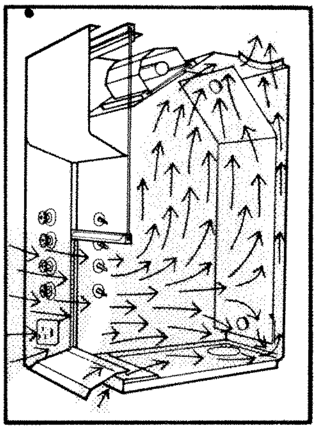
Morgan and Grundy service fittings cover the whole range of taps, valves, outlets, service boxes, service ducts and accessories that are needed to control, in an efficient way, water, compressed air, gases, electricity, steam and vacuum services in today's laboratory.



The outs

Fume Cupboards

Morgan and Grundy are specialists in the science of fume extraction and our design engineers have evolved the widest range of fume cupboards in Europe:



Lower cost, conventional fume cupboards for low risk, low duty work.

High performance, Airflow fume-cupboards which are unique in design, have patented features and are the practical result of sound engineering and accepted aerodynamic principles.

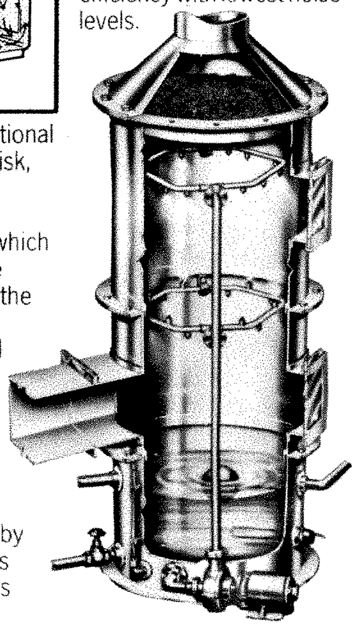
And specialised fume cupboards for every conceivable type of use.

Filters

One type of filter supplied by Morgan and Grundy cleans input air, the other removes contamination from the exhaust.
Absolute Filters can be mounted singly or in banks to remove radioactive material from exhaust gases.

Fume Scrubber

Morgan and Grundy can supply Fume Scrubbers to remove aerosoles and vapours from fume extraction exhausts.
The exhaust gases are fed into the 'wet' side of the scrubber and solution, pumped in as a fine jet at the top, is dispersed over a medium and picks up the vapour. The cleaned exhaust air is then forced up the 'dry' side of the scrubber to remove the majority of the moisture prior to releasing it to atmosphere.
All ducting systems are designed to ensure highest efficiency with lowest noise levels.



Nobody knows more about the ins and outs of good laboratory design than Morgan and Grundy. We're the largest laboratory engineers in Europe.

Don't take a chance on labelled compounds

Don't take a chance on finding the right labelled compound. We make a range of over 1500; you can bet one of them's made for you.

You needn't take chances with purity, either. Our manufacturing, Quality and Stock Control remove the risk of disappointment.

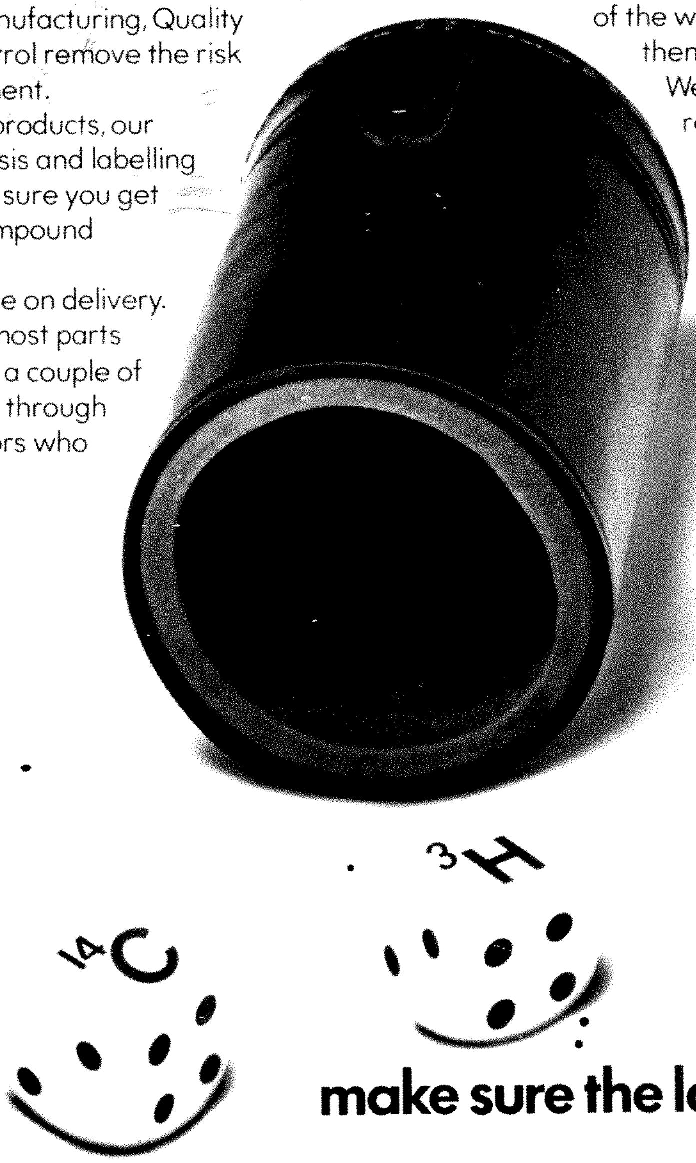
For special products, our custom synthesis and labelling services make sure you get exactly the compound you need.

Don't gamble on delivery. We deliver to most parts of the world in a couple of days. We work through local distributors who also act as our technical representatives.

Don't take risks with service. Our technical staff are on call whenever you need help. They regularly visit most parts of the world, and you can rely on them for information and advice.

We publish general interest reviews and technical bulletins. All are free on request.

Finally, here's your chance to try us. Write to us or 'phone. We'll send you our catalogue, the relevant literature and the name of your local agent.



make sure the label's ours

REVIEW ARTICLE

Homoeotic genes, compartments and cell determination in *Drosophila* — *G. Morata and P. A. Lawrence* 221

ARTICLES

Configuration of tobacco mosaic virus RNA during virus assembly — *P. J. G. Butler, J. T. Finch and D. Zimmern* 217
A model for superlight velocities of extragalactic radio sources — *R. I. Epstein and M. J. Geller* 219

LETTERS TO NATURE

A simple physical model for X-ray burst sources — *P. C. Joss and S. Rappaport* 222
Detection of change in rotation measure of the Vela pulsar — *P. A. Hamilton, P. M. McCulloch, R. N. Manchester, J. G. Ables and M. M. Komesaroff* 224
Observational consequences of synchrotron self-Compton models of compact extragalactic X-ray sources — *R. F. Mushotzky* 225
Absolute scale of thermoelectricity — *R. B. Roberts* 226
Fission/α analysis of the U, Th families — *D. E. Fisher* 227
Light-driven, carrier-mediated electron transfer across artificial membranes — *J. J. Grimaldi, S. Boileau and J.-M. Lehn* 229
Yes, Kakangari is a unique chondrite — *A. M. Davis, L. Grossman and R. Ganapathy* 230
Microbiota under Antarctic ice shelves — *J. H. Lipps, W. N. Krebs and N. K. Temnikow* 232
First Devonian platyspermic seed and its implications in gymnosperm evolution — *W. G. Chaloner, A. J. Hill and W. S. Lacey* 233
Mount gaping as an effective thermoregulatory device in alligators — *J. R. Spotila, K. M. Terpin and P. Dodson* 235
22-kHz calls by isolated rats — *R. L. Francis* 236
Specific alterations in phosphorylation of cytosol proteins from differentiating neuroblastoma cells grown in culture — *Y. H. Ehrlich, E. G. Brunngraber, P. K. Sinha and K. N. Prasad* 238
Regulation of cyclic GMP in cerebellum by a striatal dopaminergic mechanism — *G. Biggio and A. Guidotti* 240
Excitatory action of TRH on a spinal motoneurones — *R. A. Nicoll* 242
Saturation of retinal cone mechanism — *J. D. Mollon and P. G. Polden* 243

Guide to authors

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use of the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258,** 1 (1975) and **264,** v (1976).

ATP-dependent calcium storage in presynaptic nerve terminals — *N. C. Kendrick, M. P. Blaustein, R. C. Fried and R. W. Ratzlaff* 246
Chemical properties of human Ia antigens — *L. Klareskog, L. Sandberg-Tragardh, L. Rask, J. B. Lindblom, B. Curman and P. A. Peterson* 248
Recognition of a naturally occurring idiotype by autologous T cells — *M. H. Julius, A. A. Augustin and H. Cosenza* 251
Altered expression of human monocyte Fc receptors in malignant disease — *J. Rhodes* 253
Serological evidence for H-Y antigen in *Sxr*, XX sex-reversed phenotypic males — *D. Bennett, B. J. Mathieson, M. Scheid, K. Yanagisawa, E. A. Boyse, S. Wachtel and B. M. Cattanach* 255
Time and mode of fusion of human fibroblasts treated with polyethylene glycol (PEG) — *G. Pontecorvo, P. N. Riddle and A. Hales* 257
Loss of duplicate gene expression after polyploidisation — *S. D. Ferris and G. S. Whitt* 258
Common precursor pathways of Herpes DNA and of repair synthesis in ultraviolet-irradiated cells — *J. Coppey* 260
Maternal histidine metabolism and its effect on foetal development in the mouse — *H. Kacser, K. M. Mya, M. Duncker, A. F. Wright, G. Bulfield, A. McLaren and M. F. Lyon* 262
Survival of dinoflagellate blooms in the western English Channel — *R. D. Pingree, P. M. Holligan and R. N. Head* 266
Local reactivation of Triton-extracted flagella by iontophoretic application of ATP — *C. Shingyoji, A. Murakami and K. Takahashi* 269
New approach to screening drugs for activity against African trypanosomes — *A. H. Fairlamb, F. R. Opperdoes and P. Borst* 270
Feeding of *Daphnia* on *Chlamydomonas* and *Chlorobium* — *M. Gophen* 271
Chromophore mobility in bacteriorhodopsin — *W. V. Sherman and S. R. Caplan* 273
Three-chain merokeratin from wool may be a fragment of the microfibril component macromolecule — *S. S. Lotay and P. T. Speakman* 274

MATTERS ARISING

Brain tryptophan in rats on a high fat diet — *J. D. Fernstrom, H. N. Munro and R. J. Wurtman* 277
Reply — *P. H. Hutson, P. J. Knott and G. Curzon* 277
Dating earthquakes by mud profiles of lake sediments — *I. Karcz, D. Neev and I. Zak* 277
Reply — *A. Ben Menahem* 278

BOOK REVIEWS

The Humane Technologist (D. S. Davies, T. Banfield and R. Sheahan)—*Eric Ashby* 279
Structure of the Autonomic Nervous System (G. Gabella)—*R. H. Johnson* 280

You'll be pleased with all the changes that have occurred to Labex 77.

The show is being organised for the first time by Industrial and Trade Fairs Limited, (the world's largest independent exhibition organiser), by arrangement with U.T.P. Exhibitions Ltd.

The scope of the show is wider, the facilities are better – at the National Exhibition Centre, Birmingham.

Come to the new, improved Labex 77. Compare. Discover new products. Establish new sources of supply. You'll be glad you did.

If you're coming by rail the Centre's new Birmingham International station is only 80 minutes from London's Euston by fast Inter-City express. The NEC is just off the motorway with parking for over 10,000 cars, if you come by road. The airport's just across the way, too.

You can also attend the Labex lecture – a useful and informative examination of factors that affect your organisation. It's at the Metropole Hotel alongside the Centre.

Resolve to come to Labex 77 – send for your registration cards NOW!

SEARLE DIAGNOSTIC

products for research

Mouse Theta Antisera
C3H anti AKR, AKR anti C3H
CBA anti AKR, AKR anti CBA

Cultured Human Lymphocytes
Available viable or frozen

Fluorescent Theta Antibody NEW PRODUCT
C3H anti AKR,
AKR anti C3H

Mouse Ia Antisera NEW PRODUCT
10 available

Ly – 4.2 Antiserum NEW PRODUCT
SWR x Balb/c anti B10D2

Mph – 1.2 Antiserum NEW PRODUCT
Mouse Peritoneal macrophage
Alloantiserum

HLA Antisera*
36 types now available

H-2 Antisera
- Derived from cross immunisations of mouse a, b, d, f and s genotypes

Tissue Typing Plates
Glass slide with acrylic
support frame

Tissue Typing Medium NEW PRODUCT
Modified McCoy 5A

Sedimentation Reagent NEW PRODUCT
For lymphocyte separation

Anti-Lymphocyte Serum
Rat, Mouse and Human

Rat Alloantisera
Pvg anti Wag
Wag anti Pvg
Wag anti Agus
Agus anti Wag

*Not for diagnostic use in North America.

Guide to authors

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use of the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v (1976).

Allotypes of mouse IgM immunoglobulin	*N. L. Warner, J. W. Goding, G. A. Gutman, G. W. Warr, L. A. Herzenberg, B. A. Osborne, W. V. D. Loo, S. J. Black and M. R. Loken*	447
Specific glucocorticold inhibition of grown promoting effects of prostaglandin $F_{2\alpha}$ on 3T3 cells	*L. J. de Asua, B. Carr, D. Clingan and P. Rudland*	450
Altered cyclic AMP-binding and db cyclic AMP-unresponsiveness *in vivo*	*Y. S. Cho-Chung and T. Clair*	452
Prevention of senescene in the ascomycete *Podospora anserina* by the antibiotic tiamulin	*K. Esser and P. Tudzynski*	454
Solubilised viral proteins produce fatal hepatitis in mice	*A.-M. Aubertin, M. Anton, A. Bingen, M. Elharrar and A. Kirn*	456
Granulomatous hypersensitivity induced by sensory peripheral nerve	*C. L. Crawford, P. M. D. Hardwicke, D. H. L. Evans and E. M. Evans*	457
Motor neurone sprouting induced by prolonged tetrodotoxin block of nerve action potentials	*M. C. Brown and R. Ironton*	459
Punishment learning and self-mutilation in Lesch–Nyhan disease	*L. Anderson, J. Dancis, M. Alpert and L. Herrmann*	461
Peri-ovulatory synchronisation of behaviour in male and female rhesus monkeys	*R. P. Michael and R. W. Bonsall*	463
Ca^{2+}-dependent ATPase activity of bovine receptor cell outer segment	*R. A. Sack and C. M. Harris*	465
Ultraviolet light sensitivity and delayed DNA-chain maturation in Bloom's syndrome fibroblasts	*F. Giannelli, P. F. Benson, S. A. Pawsey and P. E. Polani*	466
Chromatin dispersal and DNA synthesis in G1 and G2 HeLa cell nuclei injected into *Xenopus* eggs	*A. de Roeper, J. A. Smith, R. A. Watt and J. M. Barry*	469
Evidence for cytoplasmic control of gene expression in higher plants	*G. Wolf and J. Rimpau*	470
High resolution detection of DNA-RNA hybrids *in situ* by direct immunofluorescence	*G. T. Rudkin and B. D. Stollar*	472
Anion modulation of the negative Bohr effect of haemoglobin from a primitive amphibian	*C. Bonaventura, B. Sullivan, J. Bonaventura and S. Bourne*	474

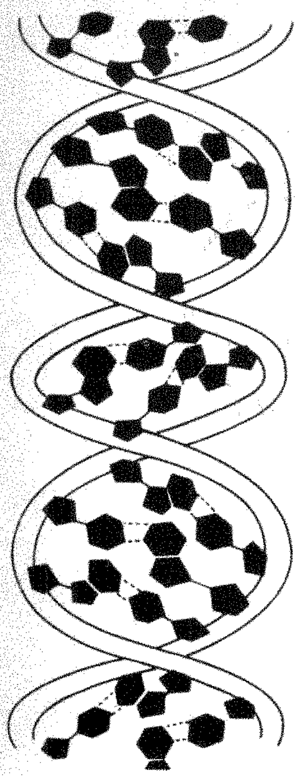
Science in Chile since Allende



"Macro-molecules! We've got you sized up and identified. And we do all our own preparative work."

(Could be a quote from any Centriscan-75 user)

The Centriscan will carry out any of the standard hydrodynamic experiments commonly used to characterise macro-molecules by shape and size. For instance:

- UV scanning absorption system
- Examination of substances which do not absorb UV light, using the schlieren technique – which is effective at concentrations even below 100 µg/ml
- Determination of sedimentation and diffusion coefficients
- Determination of molecular weight – both from sedimentation data and by equilibrium centrifugation
- Quantitative and qualitative analysis of mixtures of macro-molecular species e.g. sera, lipoproteins etc.
- Studies of nucleic acids by the isopycnic banding technique of sedimentation in Cs Cl gradients

In addition, the Centriscan 75 is an extremely versatile preparative ultra-centrifuge capable of developing over half-a-million x 'g'. It takes a 16 page catalogue (Publication 504/A) to put you fully in the picture. Send for your copy now.

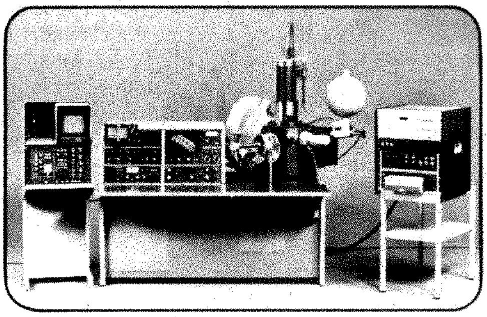
"Philips' SEM 500 gives you a lot of extras, but they make the system too expensive"

That's what some people have been saying.
Now we'll give you the facts!
If you're really serious about getting maximum information from your specimen **... it will cost you less with a SEM 500 than with any other SEM.**
Because its benefits are built-in.
Not built-on!
Cleanest high vacuum.
Automatic eucentric goniometer with the largest specimen airlock capacity.
Your choice of detection, display, recording and scanning modes.
Integrated EDAX ... interfaced for lowest noise and highest resolution.
And a fully focussing Wavelength Dispersive X-ray Spectrometer ... ideal for quantitative analysis of light and trace elements!
Plus 50 kV operation.
SEM 500 gives you more for your money. More performance. More reliability. More application support. More service.



Proof! **Seeing is believing!**
☐ Contact me for a personal demonstration.
☐ Send me further information on the Philips' SEM 500.
☐ I would like to receive your latest bulletin containing the article "X-Ray Elemental Analysis in the Electron Microscope."

Circle No. 03 on Reader Enquiry Form.

Guide to authors

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:
(i) only one reference number need be used if the reference is to several papers by identical authors,
(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963–65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use of the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v (1976).

Effect of flavone inhibitors of transport ATPases on histamine secretion from rat mast cells — *C. M. S. Fewtrell and B. D. Gomperts* 635

INSERM CONFERENCES INSERM CONFERENCES INSERM CONFERENCES INSERM CONFERENCES INSERM CONFER

The French Institute of Health and Medical Research (Institut National de la Santé et de la Recherche Médicale) is organizing a series of meetings on advanced research topics in various biomedical fields. The meetings which will be held annually as of November 1977, will be known as the INSERM CONFERENCES.

The aims of the conferences are:

- **to foster the exchange of ideas, to evaluate new methods and new lines of investigation;**
- **to bring together scientists, mostly from European countries, working in universities and public or private research institutions.**

The meetings will be held under the direct responsibility of a chairman and a co-chairman who will be chosen each year with the agreement of the Conference participants.

The INSERM CONFERENCES will have the following special features:

- **only highly topical subjects will be dealt with;**
- **if possible, the data presented should not have been the subject of any earlier complete publication, a condition which therefore excludes general reviews;**
- **the Conferences will not publish proceedings or any other material, even in a summarized form;**
- **the chairman of each INSERM Conference will invite 15 to 20 scientists to give a report in line with the above conditions. The number of contributions will be limited to three or four per session and, at the discretion of the chairman, at least one third of the time will be given over to discussion and brief informal communications.**

In addition to the invited speakers, at least fifty participants will attend the meeting, and efforts will be made to select young scientists. Experienced research workers from fields other than those relating to the Conference will also be welcome to attend. Participants will be chosen in such a way as to enable those engaged in all types of scientific research to establish personal contacts, exchange information and find new ways of working together.

PRACTICAL ARRANGEMENTS

The INSERM CONFERENCES will be held at the Domaine de Seillac, near Blois, during the month of November 1977 (full address: Domaine de Seillac, 41150 Seillac, France - 180 km from Paris). Each conference will last three and a half days, from Sunday evening (departure from Paris), to Thursday afternoon. Working sessions will be held from 9 a.m. to 12.30 p.m. and from 5.30 p.m. to 8 p.m. On free afternoons, participants will have a wide choice of leisure activities at the Domaine de Seillac and in the surrounding area.

During May 1977, the final programme for each INSERM Conference, along with the registration form will be published in this journal. Those wishing to receive additional information as of now, should complete and forward the enclosed form.

REGISTRATION FEE AND SPECIAL FUND

Participants whose applications are accepted but who are not invited speakers, will be asked to pay their registration fee and board (1000 FF). A special fund will be made available to the chairman of each Conference, enabling him to pay part of the expenses of some participants requesting such assistance.

PROGRAMME FOR 1977

The first year of INSERM CONFERENCES will include three meetings as follows:

1977 ENDOCRINOLOGY

November 7 - 10

Chairman: Jacques HANOUNE
Co-Chairman: Etienne BAULIEU

Presentations will concern the following fields of interest:

1) Recent methodological advances and new biological systems;
2) Hormonal regulation of the intermediary metabolism;
3) Membranes and transduction of hormonal information.

1977 IMMUNOLOGY

November 14 - 17

Chairman: François KOURILSKY
Co-Chairman: J.-F. BACH

Presentations will concern the following fields of interest:

1) Nature and specificity of T-cell receptors - Relationships with the major histocompatibility complex;
2) T-cell mediated cytotoxicity.

1977 NEUROBIOLOGY

November 21 - 24

Chairman: Jacques GLOWINSKI
Co-Chairman: J.-P. CHANGEUX

Presentations will concern the following fields of interest:

1) Neurotransmitters - Identification; synthesis and release processes;
2) Receptors - Characterization; isolation; molecular properties and regulation.

Additional information about INSERM CONFERENCES, along with the registration forms and conference programmes, may be requested by completing the enclosed reply form and forwarding it before April 1st to **INSERM CONFERENCES, Institut National de la Santé et de la Recherche Médicale, 101, rue de Tolbiac - 75645 PARIS CEDEX 13, France** - Tél. : 584.14.41.

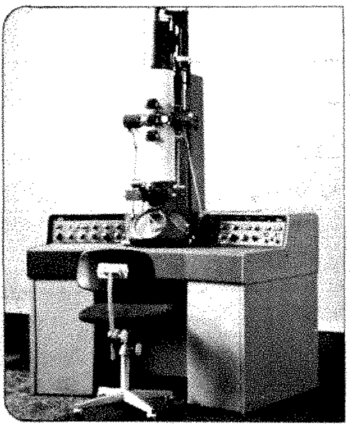
“Adding a bigger pump will give you a clean high vacuum as good as Philips’ EM 400”



That’s what some electron microscope makers are saying. They’re wrong.
We can prove it.
Designing an electron microscope isn’t like decorating a Christmas tree.
What matters is what you begin with.
Not what you add on afterwards.
Protecting your specimen from contamination and erosion (what clean high vacuum is for) demands more than cutting down Torr values.
You’ve got to cut hydrocarbon and water vapour partial pressures.
This means becoming clean high vacuum specialists.
We have.
That’s one reason why the EM 400 gives you more information from your specimen than you’ve ever had before.
Why you can’t afford “patch-up” solutions!

Proof!
Seeing is believing!

☐ Send me your new bulletin featuring “Clean vacuum systems for electron microscopes.”
☐ Send me further information on the EM 400.
☐ Contact me for a personal demonstration.

Back to the freeze?

A COUPLE of years ago (January 10, 1975) we reported on an extremely gloomy set of figures which showed how openings for senior university posts in the United Kingdom had all but disappeared in 1974 as a result of a general freeze in hiring. We have now brought the figures up to date by analysing advertisements for the years 1975 and 1976. Things are, at least temporarily, much better.

In the past two years the level of hiring seems to have been back fairly close to the levels of the late 1960s and early 1970s. Of course this indicates that the backlog has not been, and is never likely to be cleared. Some posts have disappeared for ever. But it may help to shake loose, in the course of time, the rigidity with which the universities were beginning to be afflicted. That is, unless the next rather ominous cloud on the horizon can be dispersed.

That cloud is the recent warning by the University Grants Committee that next year's (1977–8) grant to universities for salaries, maintenance and capital expenditure could be as much as 4% down in real terms. This figure first appeared in mid-1976 when the raising of student fees was seen by the Department of Education and Science not only as a way of bringing in more revenue to universities but also as a restraint on growth in student numbers and therefore in university financial needs. Since then there has been much re-adjustment, including the recent public expenditure cuts, but the result of it all is that we are back to the figure of 4% as the basis for discussion and warning.

Three quarters of all UGC disbursements go on salaries and so the next round of the national pay policy, not yet openly discussed, could make the figure look disastrous—or even quite tolerable; such is the uncertainty in which universities, once used to quinquennial planning, now live. But whatever happens there is a limit to the amount that can be saved by not painting, not cleaning and not heating. Very soon we could be back to solving the universities' financial problem by again venturing on the capricious course of not hiring. ☐

Amaze, test, shock your friends

THE festive season permits us to see ourselves as others see us and no better than through the scientific books, toys and kits showered on our children—and ourselves.

Here we have a book in which it says that if you drop a slice of buttered bread from a height it will land more often with its buttered side down. This is because the layer of butter makes one side heavier so "there is a tendency for the butter-side to fall faster". Yet further on we are told that in the absence of air "heavy things and light ones get up speed with the same degree of acceleration". And to complete the confusion we hear about a lorry with a load of canaries. When the birds all fly up in their cages "the weight on the tyres is reduced".

Or here is an excellent planisphere to show the position of the stars. The stars, it says on the back "appear to move in the same way as the sun" except that the "apparent movement of constellations near Polaris is more limited". And your absolute beginner, venturing out just after Christmas in the early evening might wonder why a couple of the most prominent 'stars' in the sky don't rate a mention.

They do get mentioned elsewhere in an encyclopedia for boys and girls. "The Universe is made up of the Earth we live on, the Sun and its other planets, thousands of other small bodies—and space itself . . . a planet is a big ball of rock and gas".

Nothing about astronomy in the Super Quiz Book for Girls; the question on stars runs "where were Paul Newman and Omar Sharif born?" In the same book there is a picture of a lady in a white coat which bears the label 'UKAEA'. A machine is applying lipstick by remote control—"Of course, the machine was developed for handling radioactive materials, but something like it may well one day be in every home". The same quiz book also offers intelligence tests—"use these tests to see how much quicker and brighter you are becoming, how you compare with your friends".

Home experiments seem to have become simpler and certainly safer with the years. No longer do you "hold the two handles of the induction coil and gradually insert the steel rod until you can no longer bear the tingling sensation. Compare your performance with that of your friends". But even a book of delightfully simple experiments has an oddity or two. Place a bottle between your mouth and a lighted candle. Why does the flame go out when you blow? "The air moving past the bottle creates a partial vacuum behind the bottle, and the air rushing in to fill this vacuum puts out the flame".

After junior science, the children can at least retreat into the unambiguous world of their first knitting kit—"Place a needle under your left arm. Hold the end of the yarn tightly in your left hand. Take the yarn coming from the ball into your right hand between your thumb and middle finger. Turn your index under the yarn between your hands towards you and point your index forward. There is a loop on your index". ☐

Articulating the aims of science

Nicholas Maxwell, of the Department of History and Philosophy of Science at University College, London, offers this comment on the current state of the art

MODERN science is, I suggest, seriously harmed by a widespread attempt to make science conform to a wholly inadequate philosophy of science—a philosophy of science which quite grotesquely misrepresents the basic intellectual aims of science.

This indequate philosophy of science may be called 'standard empiricism'. It is carelessly and unthinkingly taken for granted by the scientific establishment today. It is defended by almost all contemporary philosophers of science—from Popper to Kuhn, Lakatos, Hesse and Grünbaum—as constituting a rigorous, rational conception of science, even though elementary arguments show decisively that the view fails miserably to exhibit science as a rational enterprise.

The basic idea of this philosophy of standard empiricism is that the fundamental intellectual aim of science is simply to improve our knowledge of value-neutral factual truth, scientific progress being assessed in terms of how successfully this aim is being realised. *A priori* knowledge about matters of fact being denied, it is held that in science theories must be assessed, in the end, solely in terms of empirical success.

In fact, of course, science does not seek to improve our knowledge of factual truth as such; rather, quite properly, science seeks to improve our knowledge of *important* factual truth, truth that we deem to be in some way valuable, significant, interesting, beautiful, useful, from either a cultural or a practical, technological standpoint. Progress in science is assessed in terms of the amount of valuable factual truth that is being discovered: accumulation of trivia, however extensive, does not, and ought not, to be judged to amount to progress.

Once it is acknowledged that a basic intellectual aim of science is to discover valuable truth, it becomes clear that the aims of science must remain permanently and profoundly problematic. What is there to discover that is, in one way or another, valuable or useful? In what direction do really important, exciting future discoveries lie? What ought to be the general priorities of scientific research? What is at present of greatest importance or value, from a human, social standpoint? Important to whom? What kinds of things will we most need to know in fifty or one hundred years' time? These questions are all highly controversial and problematic just because they concern the domain of our ignorance, and difficult issues concerning human needs, aspirations and values.

It is of fundamental importance that we make the best possible choice of aims for science; and it is almost inevitable that we will fail. Here above all, then, we need to proceed intelligently, critically, imaginatively, wisely. If science is to proceed in a truly rigorous and rational fashion it is essential that we articulate, explore and criticise possible and actual aims for science as an integral part of scientific enquiry, providing ourselves with a wealth of critically examined alternatives, so that we may enhance our capacity to choose wisely and well. Quite generally one can say that rigour involves making explicit and so criticisable that which is implicit, influential and problematic. The best aims for science lie in the direction of the overlap between that which is scientifically realisable, and that which is humanly desirable. In order to give ourselves the maximum chances of discovering this problematic region of overlap we need to articulate both that which we conjecture to be scientifically realisable and that which we conjecture to be humanly desirable.

A truly rigorous, rational science would, then, include three kinds of contributions to science. In addition to contributions at the level of experiment and theory, we need to include contributions which articulate, explore and criticise possible aims for science. Scientific journals, textbooks, and educational courses need to include a discussion of all three kinds of contributions. It ought to be possible to win a Nobel prize by a sufficiently brilliant contribution at any of these three levels. We need to regard our scientific knowledge as consisting not only of what we know, but also of our best conjectures about what we do not know, but hope and desire to discover. We are never completely ignorant of that which we do not know; for if we were, we could have no basis for our assumption that the domain of our ignorance will not suddenly intrude upon the domain of our knowledge in some violent, unruly fashion, entirely disrupting the straightforward predictions of our present day scientific theories. Without some vague knowledge of that of which we are ignorant, all scientific knowledge would be impossible.

All this was well known to Einstein (*Ideas and Opinions*, Souvenir Press, 1973). He understood clearly that theoretical physics is only a worthwhile, rational enterprise when pursued as an attempt to discover a conjectured unified harmony in nature, the basic aims of physics thus being permanently and profoundly problematic. The success of Einstein's contribution to physics arose in large measure from his ceaseless concern to articulate and develop the best possible aims for physics, taking into account both existing knowledge and our desire to discover unity and harmony, appropriate heuristic rules then being formulated as guidelines to the development of new theories. I suggest that this kind of aim-oriented empiricist methodology, exploited with such success by Einstein within the restricted field of theoretical physics, is of universal relevance to science and technology.

At present aim articulation, as envisaged here, does not proceed as an integral part of scientific enquiry, just because most scientists take standard empiricism for granted. Once standard empiricism is accepted, scientific rigour and rationality actually seem to require that articulation and discussion of possible and actual aims for science be excluded from the intellectual domain of science. Thus, as a result of the attempt to make science conform to the intellectual ideals of standard empiricism, scientists have served to undermine the rigour and rationality of science, precisely because the vital task of articulating and exploring possible aims for science has been somewhat inhibited and repressed. As I have argued in greater detail elsewhere (*Phil. Sci.*, **41**, 123–53, 247–95 (1974); *What's Wrong with Science?*, Bran's Head Books, London, 1976), there is at present an urgent need for the scientific community to free science from the irrational ideals of standard empiricism, and to put into practice the kind of aim-oriented empiricist conception of science so successfully practised by Einstein. □

Gemona: the reckoning

An earthquake struck Gemona di Friuli, Italy, last May. **Nick Ambraseys** assesses its impact

THE Gemona earthquake of May 6, 1976, affected a large region in North-East Italy which, during the past nine centuries, has been devastated by a series of large shocks that have had recurrence intervals of almost total quiescence of 150 to 200 years. The largest of these events occurred on January 25, 1348, and on March 26, 1511. These earthquakes were associated with radii of perceptibility of 650 to 750 km and with aftershock sequences that lasted from three to six months. In addition, the shock of 1348 triggered a slide in the Gail valley, the volume of which exceeded 1,000 million m^3, a volume about four times larger than that triggered in 1963 at Vajont by the rapid draw-down of the reservoir level.

The Gemona earthquake occurred at 2100 hours local time near 46.24°N 13.28°E and had a focal depth of less than 10 kilometres; it had a surface-wave magnitude of 6.3 and was preceded by a single foreshock of magnitude 4.5. Another phenomenon which could have been premonitory was the appearance of a glow in the sky above the northern part of the epicentral region which persisted for some time after the earthquake.

There is no evidence that the earthquake was associated with surface faulting. Ground deformations originally suspected to be of tectonic origin in Montenars, Sedilis, Susans and Avasinis proved on examination to be of secondary nature. Persistent patterns of ground fracturing caused by slumping do not align with any minor or major fault.

The earthquake produced ground fracturing on flat and sloping ground, as well as a few cases of very local liquefaction. Landslides, rockfalls and debris-flows from steep slopes triggered by the shocks and heavy rains caused serious damage to property. Most of the rock faces and slopes that collapsed were already unstable.

More than three-quarters of the houses in the region are very old. Their walls consisted of coarse, short-bedded, badly-laid rubble masonry, sometimes mixed with bricks and with great thicknesses of lime or clay mortar joints, concealed by plaster or rough cast. Floors and roofs are heavy, resting on joists of timber. The use of tie-rods in masonry walls and laid at floor and roof level has saved many houses from collapse. New houses, mostly those built with some care after the local shocks of 1928 and 1939, have brick walls and reinforced concrete columns with cast-*in-situ* slabs. These houses, as well as structures built more recently with few openings and light roofs, survived the shock with comparatively little damage.

Both old and new houses which had recently been renovated suffered the most. A common cause of unintentional weakening was found to be due to the installation of electricity and water conduits in old houses, the re-location of bathrooms and sewer and drainage pipes in old walls, and the addition of extra rooms and floors in old dwellings. Damage to only less than a quarter of the houses in the region could have been prevented had modern houses been built to resist earthquakes; the rest were built long before the advent of modern technology. Lack of ductility and eccentric stiff structural elements in open ground floors were the main cause of damage to modern reinforced concrete houses and blocks of flats. Prefabricated constructions particularly in the industrial areas suffered more than other types of structures. The affected region was not considered to be highly seismic and very few buildings had been designed and built to resist lateral forces.

Within the region of maximum damage, intensities varied erratically from place to place and in only a few isolated points did they reach an intensity IX on the Mercalli scale. In this region the distribution of damage was influenced more by the type of structures shaken than by their foundation conditions. Intensities underground were much smaller than those experienced on the surface. In deep caves, delicately poised rocks, thin stalactites and stalagmites showed no signs of disturbance.

The maximum horizontal ground acceleration deduced from displaced objects in the meizoseismal region reached values of $75\%g$ associated with very high frequencies. The peak acceleration of the main shock recorded at a focal distance of about 30 kilometres (S—Start time=3.8 sec.) was $37\%g$ and the velocity 32 cm sec^{-1}. Peak accelerations of aftershocks of magnitude 5, recorded at smaller distances, reached values in excess of $50\%g$.

The main shock killed 965 and injured 2,286 people. The average rate of fatalities for the whole area is just under 1% of the affected population. All age groups except the infants and elderly suffered fatalities roughly proportional to their numbers. In densely populated villages and in historical town centres the more agile group of youths suffered more casualties in their attempts to seek refuge outdoors into narrow streets where they were crushed under falling walls.

The damage caused by the main shock was estimated late in May at $1,707 million. Damage to dwellings was $573 million, to agriculture $488 million, to industry $244 million, handicraft industry $146 million, public buildings $122 million, commerce $110 million, roads $16 million and aqueducts $8 million.

Preliminary estimates today for the total damage caused by the main shock and its aftershocks including loss of revenue from commerce amounts to $2,859 million. The total loss to buildings which includes 237,000 rooms of houses which were either totally destroyed or seriously damaged (excluding contents) has been estimated at $1,078 million. This figure is based partly on August–September 1976 market replacement values and partly on assessed

Destruction at Friuli

values. It includes replacement cost for 1,650 hospital beds and for seriously damaged or destroyed public buildings. Damage to industry, including handicraft and small industry is estimated at $599 million. Damage to agriculture amounted to $479 million which has now risen to $610 million.

Damage to public works and utilities amounted to $240 million including repair costs for the water supply, sewers, electrical facilities, aqueducts, road and railway communications. Loss of revenue from commerce is estimated at $240 million, and $176 million will be required for the repair and extension of the flood control of the Tagliamento valley. There is $49 million-worth of damage to school buildings and a sum of $96 million has been allocated for the repair of the few historical monuments that survived the shock. About 600 churches were destroyed or damaged beyond repair and damage to historical buildings, castles and works of art cannot be calculated.

One of the conclusions that can be drawn from the study of the Gemona earthquake is that this event could easily have been expected from what we know about the seismicity of the region This earthquake demonstrated once more the economic vulnerability of developed and densely populated regions of apparently low seismicity to strong earthquakes of long return period but short recurrence interval. It also demonstrated the need for the application in such regions of minimum earthquake resistant design requirements in the construction of new buildings and for the strengthening of old ones, particularly of historical monuments and art treasures. The amount and extent of damage caused by the earthquake and by its aftershocks have important implications for the insurance industry and for the social and economic planning in earthquake areas. □

The field work reported in this study constitutes part of the work carried out on a UNESCO Earthquake Reconnaissance Mission to Friuli (Ambraseys N., "The Gemona di Friuli (Italy) earthquake of May 1976", *UNESCO Rec Mission Report*, No 273 182 (1976), UNESCO, Paris). The writer would like to record his indebtedness to the President of the Regione, Dott A. Comelli, the Director of Forestry, Dott. R. Querini and to the Vigili del Fuoco for their generous cooperation.

Prediction: the negative aspects

The ability to predict earthquakes should reduce deaths, injuries, and property damage, but the prediction itself can have some negative effects. Henry Lansford sent this report from Boulder, Colorado, on a new study of the socioeconomic impacts of earthquake prediction:

WHEN social scientists go out into the real world to study a subject that has attracted a good deal of public attention, they usually come up with two classes of conclusions. The first class includes unsurprising findings that often provoke sceptics to snort that social science research is a waste of time—"common sense would have told you *that*!" But in addition to confirming some things that common sense might suggest, good social science research can turn up some surprises too—the unexpected insights into human behaviour that the sociologists like to call "counter-intuitive conclusions."

An 18-month study[*] of the potential impacts of earthquake prediction in the United States, conducted at the University of Colorado with support from the National Science Foundation, has produced both kinds of conclusions. The research team concluded, for example, that although the first credible predictions of damaging earthquakes months or years before they occur can save many lives and reduce property losses, such predictions can also result in severe economic depression and social disruption in the communities for which earthquakes are predicted. Although nobody had given much thought to this negative aspect of earthquake prediction, it should not come as a great surprise that property values and tax revenues will decline in an area for which an earthquake is predicted; that business activity, employment opportunities, and public services will be reduced; and that the sale of earthquake insurance policies will cease as soon as the prediction is issued.

But there are also some counter-intuitive conclusions. The researchers found few indications that homeowners who have small equities in heavily mortgaged homes would simply walk away and stop making their monthly payments, contrary to what common sense with a touch of cynicism might suggest They found that savings deposits in banks in the "target community" for which the earthquake is predicted would go up instead of down with the rest of the economy, as people save money instead of spending it on household appliances or other property that might be damaged or destroyed by the earthquake. And, perhaps most surprising of all, they found that 40% of the residents would remain, rather than evacuating either temporarily or permanently, in an area for which an earthquake five times as great as the one that devastated San Fernando, California, in 1971 has been predicted, even if they believe that the prediction is accurate.

The research team, which included both physical and social scientists, did most of their field work in California, which has had more recent experience with earthquakes, as well as more trepidation about future ones, than any other part of the United States The team also looked closely at earthquake-prediction research that has been going on in China, Japan, and the Soviet Union. They began by getting estimates from seismologists of the probable characteristics of the first official, scientifically-based earthquake prediction in the United States and of the way in which it would probably be released to the public. Then they formulated two "prototype" predictions: one assumed a five-month lead time, a 50% probability of occurrence, and an earthquake with a magnitude of 6.3 on the Richter scale; the second assumed a three-year lead time and a 7.3 magnitude. Then they conducted more than 1,000 interviews throughout California, with federal, state, and local government officials, executives of large and small businesses, managers of large and small news media and individual families.

Three of the study's findings are regarded as particularly significant:

- Under existing laws, it is not clear whether federal disaster-relief funds can be committed on the basis of an official earthquake prediction or whether it will be necessary to wait until earthquake damage has occurred before committing funds that might have helped prevent the damage
- No workable alternative to earthquake insurance exists for indemnifying those whose property is damaged or destroyed by an earthquake, although the California state insurance commissioner has stated that he will stop the sale of new earthquake insurance policies in any area for which a credible official earthquake prediction has been issued.
- Damage estimate maps, based on solid scientific data and published by news media in the threatened area, should reduce property damage considerably if the earthquake prediction provides enough lead time to reinforce structures and undertake other damage-prevention measures. □

USSR

What sort of turning point?

Vera Rich reports on the fate of dissident Soviet scientists in light of the recent release of Vladimir Bukovskii.

THE release of Vladimir Bukovskii, in "exchange" for the Chilean Communist leader Luis Corvalan, brings to the West one of the most significant figures in the human rights movement in the Soviet Union. It does not, however, appear to indicate any general amelioration of the plight of dissidents; indeed, following Bukovskii's release, a number of other dissidents and refusniks, including several prominent scientists, were arrested.

Bukovskii, who was first arrested in 1963 while still a student of biology, has spent ten of the last thirteen years in penal psychiatric hospitals, prisons, and strict regime labour camps. During one of his brief periods of freedom he managed to inform the outside world of the growing Soviet practice of employing psychiatric methods to repress political dissidents, thereby posing an ethical problem to Western psychiatrists as to what should be their professional relationship (if any) with those of their Soviet colleagues known to be involved in this abuse. Imprisoned once again, in 1974 Bukovskii was sent to the strict regime labour camp at Perm', where with his fellow prisoner, the psychiatrist Semeon Gluzman, he wrote the now-famous *Manual of Psychiatry for Dissidents,* which sets out self-defence strategies for those whose political or ethical convictions are judged by the authorities to be evidence of insanity.

Immediately on his arrival in Zurich, Bukovskii thanked those who had campaigned for his release and announced his intention of devoting the rest of his life, if necessary, to campaigning for his fellow prisoners-of-conscience. In the euphoria of release, he said that he felt his liberation marked an important new trend in Soviet policy and was "a great victory for everyone". This hope, however, does not appear to have been justified. The "exchange" procedure which brought Bukovskii freedom has been tacitly denied by the Soviet authorities; officially, Corvalan was released due to the efforts of "progressive forces" throughout the world, while Bukovskii was expelled from the Soviet Union as a terrorist. And, a few days after Bukovskii's release, another former long-term psychiatric detainee, the electrical engineer Vladimir Borisov, was rearrested.

Borisov, who was released in 1974, had spent the major part of the previous eleven years in penal psychiatric hospitals for having organised an unauthorised youth group. During his captivity, he took part with Viktor Fainberg in a hunger-strike to protest against the conditions under which the prisoners are kept and the denial of their basic rights. Borisov's rearrest, on December 25, was allegedly in connection with the anti-Soviet slogans which appeared on walls in Leningrad earlier this year; dissident sources in Leningrad, however, interpret it as a warning from the authorities not to assume that Bukovskii's release marks a new 'thaw'. Borisov is at present, confined in a Leningrad psychiatric hospital in a block for 'acute' and violent cases, and has not yet been seen by the 'commission' of three psychiatrists which, legally, must decide on his case. His wife Irina is demanding that the commission should consist of psychiatrists whom she can trust, and has asked for Semeon Gluzman, Marina Voikhanskaya, and Gary Low-Beer.

This request is unlikely to meet with official approval. Dr Gluzman is still in the Perm' labour camp, where he was sent for exposing the 'official' diagnosis of insanity in the case of General Grigorenko. Dr Voikhanskaya, who formerly worked in the hospital where Borisov is now confined, was obliged to emigrate (leaving her young son behind) after her repeated refusals to administer psychotropic drugs to dissidents. Dr Low-Beer, of Horton Hospital, Epsom, a prominent campaigner against the political misuse of psychiatry, told *Nature* that he is quite willing to comply with Mrs Borisova's wish that he should examine her husband, and that although it is virtually impossible that the Soviet authorities would allow such a commission to decide Borisov's fate, he himself would press for and demand the right of access to the 'patient'.

Unlike Borisov's arrest, the arrest and harassment of some 45 Jewish refusniks in Moscow (including the physicists Mark Azbel and Aleksandr Lerner, the mathematician Viktor Brailovskii, and Academician Veniamin Levich, an electrochemist) is not directly associated with the release of Bukovskii. The group, members of the now-famous Sunday seminars for dismissed scientists, had been under pressure for some weeks following the announcement of their intention to hold a symposium on Jewish life and culture in the Soviet Union. (A growth of Jewish consciousness is, not unsurprisingly, a common phenomenon among the refusniks).

Vladimir Bukovskii

The group had been warned that if they persisted in going ahead with their plans, the authorities would take action. The threat was reinforced by a vicious attack in *Izvestiya* on Aleksandr Voronel, the founder of the group, who emigrated to Israel in December 1974; this called him a "former scientist without a future, indeed without a present", a "trader in human souls" and an "unmasked provocateur". The article recalled how, in summer 1974, Voronel's efforts to hold an international session of the seminar "failed completely"—as indeed it did, since would-be participants from abroad were refused visas and the "hosts" were arrested or subjected to severe harassment. A repetition of these tactics in the case of the Jewish symposium was therefore expected; it was hoped, however, that the authorities would intervene simply to break up the symposium, and that there would be no long-term arrests.

This, unfortunately, has not proved to be the case. Criminal proceedings have commenced against one of the would-be participants, the physicist Naum Salanskii from Vilnyus, on the grounds that the paper he had prepared for the symposium slandered the Soviet Union by giving incorrect information about the treatment of the Jewish minority. In Leningrad, a Jewish mechanical engineer, Vladimir Shverdlin, was arrested on a charge of unlawful possession of weapons (apparently a few bullets left over from his membership, some years back, of a shooting club); although he has since been released, his family have been informed that the results of the investigation have been "passed on to the Procurator".

In spite of such warnings, the human rights campaign still continues. Following the arrest of Borisov, a group of eighteen Moscow dissidents has called for a renewed campaign against the political abuse of psychiatry. In Kiev, a 'Helsinki monitoring group' has been set up, similar to that set up earlier this year in Moscow; its members include Nina Strokata-Karavans'ka, a microbiologist, and the science-fiction writer Mykola Rudenko. □

USA

● President Ford's final budget, which is expected to be delivered to Congress on January 17 (just three days before his successor is inaugurated), will promise large increases in funds for research and development and propose that the green light be given to several important and eagerly-awaited scientific projects. Though it's possible that the whole budget document could be turfed out by the incoming Carter Administration, Mr Carter will have more pressing matters on his mind than tinkering with the nuts and bolts of the federal government's science programmes; it is therefore likely that some of Mr Ford's lame-duck proposals will survive more or less intact.

The rough outline of the proposed budget for research and development was sketched out last month by Guy Stever, the President's science adviser, who is also about to leave the government. Stever called a press conference after meeting to discuss the budget with Mr Ford, a number of prominent people from the scientific community and government officials from science agencies. He announced that Ford will propose that basic research be given a real increase, amounting to about 3% above the rate of inflation, in the fiscal year which begins on October 1, 1977, and that some of the increase would be spent on new projects in agricultural research, space science and earthquake prediction.

Following the pattern established in his two previous budgets, President Ford will propose particularly large increases in military science and technology and energy research and development. The proposed increase in military science alone will amount to about 15%, Stever said. Carter will take a close look at both those two areas, however, and Ford's proposals should therefore be taken with more than a pinch of salt.

As for space science, the proposed budget will contain some good news for astronomers and planetary scientists. Last year, in an effort to reduce public expenditure, the Ford Administration stripped about $200 million from the budget of the National Aeronautics and Space Administration shortly before it was sent to Congress, and NASA was consequently forced to defer plans to build the Large Space Telescope (LST) and to start work on a spacecraft to orbit Jupiter. Those funds will be reinstated in this year's budget, however, and if approved by the Congress and by the Carter Administration, the LST should be ready for launch in the early 1980s and the Jupiter mission will be launched in 1981. Both missions rank high on the list of priorities for space research drawn up by the National Academy of Sciences.

Another space project which Ford will approve is construction of a fourth satellite in the Earth Resources Technology Satellite series, called Landsat-D. The Landsat programme has consistently received strong support from Congress, and Ford's proposals will probably be accepted.

The lame-duck budget will also include a large helping of money for earthquake research, another area in which Congress has taken an interest. President Ford will propose that funds for earthquake monitoring and prediction be doubled in the next fiscal year, to reach about $50 million. The money would be divided between the US Geological Survey, which operates a number of seismic stations and research establishments in California, and the National Science Foundation. No details are available of the projects which will benefit from this largesse, however.

Finally, in agricultural research, President Ford has decided to implement a proposal which has been advanced by three committees of the National Academy of Sciences and by two committees of the House of Representatives. He will propose the initiation of a new programme of competitive grants, funded through the Department of Agriculture, for basic research related to agriculture. The new programme, which would receive about $35 million next year under Ford's proposal, will complement rather than replace the Agriculture Department's traditional block grant system for agricultural research.

Usually, budget details are not released until the proposals are sent to Congress, but in this case, the tradition was broken presumably because the figures for research and development look good. Since Guy Stever and the Office of Science and Technology Policy can claim a good deal of the credit, they were understandably keen to get the word out before Stever departs.

● The National Academy of Sciences has finally added its voice to the chorus of criticism directed at the so-called 'hot particle' theory. Put forward in 1974 by Drs Thomas Cochran and Arthur Tamplin, staff scientists at the Natural Resources Defense Council, the theory is that tiny particles of inhaled plutonium may lodge in the lung and deliver a prolonged, intense dose of radioactivity to a small area of surrounding tissue, thereby posing a severe cancer hazard. NRDC argued that since present plutonium exposure standards are based on average doses of radioactivity to the entire lung, they underestimate the health hazards and should be tightened by a factor of about 115,000. Such strict standards would present a problem for reprocessing and plutonium fabrication plants.

In a report published last month, however, an Academy committee concludes that the evidence doesn't support the hot particle theory and that there is no need to lower plutonium exposure standards. The committee, which examined the theory under contract to the Environmental Protection Agency, looked at the results of tests on beagle dogs and concluded that the observed incidence of cancer doesn't fit in with the hot particle theory, and suggested that it "can adequately be accounted for by averaging the absorbed alpha radiation dose over the whole lung." The committee also argues that epidemiological evidence from experience with inhaled alpha-emitting particles suggests that the usual method of applying an average radiation dose to the whole lung to predict carcinogenic effects.

Colin Norman

FRANCE

Deceptively generous budget

The staff of La Recherche *report from Paris on the funding for research in France in 1977*

THE National Assembly and Senate of the French parliament have just approved the budget for scientific research for 1977—that is, they have approved the provisional calculations of expenditure for the 'enveloppe recherche' presented by the Minister for Industry and Research. But this budget package, since it does not take into account military research or telecommunications, is only a fabrication.

As early as the end of May last year, the first draft of the 'enveloppe' had been strongly criticised by the consultative Committee on Scientific and Technical Research. M d'Ornano had then managed to get some adjustments to it through the Ministry of Finance. He finally obtained 10,935 million francs, an increase of 18% on last year's budget of 9,262 million francs. The major portion of this sum goes as usual to the Atomic Energy Commission (FF2,783 million), the National Centre for Space Research (FF1,014 million) and to information processing (FF725.6 million). The National Centre for Scientific Research receives FF2,555 million.

The budget is larger, however, only because more jobs have been created. And it must be remembered that the package is already cut into by international commitments and by other expenditure unconnected with research. For the National Centre for Space Research, for example, FF586 million is reserved for multilateral programming, such as the programmes operated within the European Space Agency like Ariane, Marots and Spacelab. For information processing, on the other hand, FF450 million is allocated to CII–Honeywell-Bull.

The government has decided to create 950 new posts, of which 437 would be for research, and the rest technical or administrative. Furthermore, 900 people, 95 of them research workers, will benefit by the integration of 'hors statut' personnel. (Staff who

ISRAEL

• Israel's universities have spawned a new political party which threatens the local establishment more seriously than it has been threatened in many years. If present trends continue, the recently formed Democratic Movement of the Hebrew University archaeologist Yigael Yadin, and other reformist groups close to it, may well emerge as the strongest bloc in Israel's Knesset after the 1977 elections, perhaps even making it possible for Yadin to become the next Prime Minister. The elections are being held sooner than expected with the early end of Mr Rabin's government.

Yadin offers very little that is new in the policy sphere. Like large sections of the hitherto dominant Labour Party, he favours a compromise settlement with the Arabs, electoral reform and stringent measures to stabilise the economy. But he has the advantage of being a political outsider, untainted by the corruption and dissension that has beset Israeli public life in recent years.

This is not to say that Yadin has been an academic recluse in the quarter century since his retirement as Israel's second chief of Staff. On the contrary, his highly successful digs at Hazor in the Galilee and at Massada on the Dead Sea were well publicised, as was his service on such non-partisan bodies as the Agranat Commission (which investigated aspects of the Yom Kippur War). This makes him particularly attractive to the many Israelis who ardently desire "to throw the rascals out", but want to be sure that "the rascals" are replaced by men of experience and competence.

Yadin is by no means the only Israeli don to have played a part in public life: Israeli's first President, Dr Chaim Weizmann, was a distinguished chemist, and her current President, Professor Ephraim Katzir, headed the Weizmann Institute's Biophysics Department for many years. But the Presidency is largely a ceremonial post, and this is the only time that a savant has tried to exchange his academic robes for the powerful mantle of the Prime Minister.

• A central plank in Yadin's platform is his insistence that Israel remain a predominantly Jewish state, meaning that many of the Arab-populated areas now under Israeli control would, if he had his way, be relinquished within the framework of a peace settlement. This being the case, Yadin favours concentrating long-range development efforts on those parts of the country where the Arab population is sparse, with particular emphasis on the virtually empty Negev desert between Beersheba and Eilat.

Thanks to the discovery of a vast underground lake running from the Dead Sea to the middle of the Sinai Peninsula, it now appears that the Negev can be developed more rapidly and extensively than hitherto appeared possible. The Mekorot Water Company has carried out drillings in the wake of preliminary studies by scientists from the Ben-Gurion University of the Negev and the Weizmann Institute. Company officials speak of at least 200,000 million cubic metres of water at depths of between 800 and 1,000 metres. Initial tests indicate that the water has from 500 to 2,000 p.p.m. of minerals, which means that some of it can be utilised immediately, while other water will have to be processed through reverse osmosis or electrodialysis installations.

Water from the Negev 'lake' must be exploited carefully, as it is not likely to be replaced for quite some time. Most of it, according to carbon-14 dating tests, stems from the precipitation that occurred 20,000 years ago during the last Ice Age, when rainfall in the Negev averaged 1,000–3,000 mm a year, as compared to some 100 mm today.

• Rainfall now, it turns out, is heaviest where it is least needed, in Israel's urban areas. A recently completed study of climatic conditions in the Tel Aviv area over the last 30 years carried out by Dr Yair Goldreich of Bar-Ilan University and Alexander Mannes of Israel's Meteorological Service showed that rainfall had increased by 5–17% as compared to the rest of the countryside.

This study indicated that heat generated by greater radiation from concrete, asphalt and other built-up surfaces weakened the frequent temperature inversions of the air above the city, creating unstable conditions conducive to rain. At the same time, the greater currents of air caused by this heat and also by tall buildings contributed further to increased precipitation.

Another conclusion of the study was that growing air pollution in the Tel Aviv area, where population has tripled in the past 30 years, had caused a drop of 7% per decade in the amount of solar radiation reaching the ground.

Nechemia Meyers

are 'hors statut' are employed on contract for a limited period, whereas usually, in 'la recherche publique', researchers have the status of a civil servant, and are therefore guaranteed tenure).

There is also to be a large increase in the funds allocated to university research, due to go up from FF76 million in 1976 to FF120 million in 1977. This increase will rekindle the enthusiasm of the professors, who in return are urgently asked to put the affairs of the State Secretariat for Universities in order.

The research priorities of the Seventh Plan are, of course, the best safeguarded. Among these is research to reduce France's dependence on other countries for energy and basic materials. So FF195 million will be spent on providing new energy sources, and FF45 million on uranium prospecting. In addition, special efforts are to be made to improve food production, scientific and medical instrument manufacture, prevention of pollution, and cooperation with underdeveloped countries.

It is indeed a budget which is misleading in its generosity, but which follows well-marked political intentions. □

SOUTH AFRICA

●South Africa is to embark on the construction of a 200 MeV open sector cyclotron early in 1977, thanks to the award of a government grant of R570,000 (£1=R1.45) for the next stage of the project. This is in addition to the more than R200,000 already spent on feasibility studies.

The facility, which will be built near Cape Town, has been 4 years in the planning and is expected to be operational in 1983. In due course the cyclotron and its staff will absorb the functions of the present Southern Universities Nuclear Institute at Faure, and progressively replace the CSIR's cyclotron, which is expected to have a lifetime of only a further 6 years. The new cyclotron will be used primarily for the production of radioisotopes for medical research, for radiotherapy, and for nuclear physics research.

Responsibility for the facility will be vested in an independent company, still to be set up, the funding for which is likely to come directly through the office of the Prime Minister's Scientific Adviser.

●The Prime Minister's Scientific Adviser, Dr S. Meiring Naudé, will retire at the end of the year. His successor is to be Dr A. P. Burger, a former director of the National Research Institute for Mathematical Sciences and currently a vice-president of the CSIR. Dr Naudé, a former president of the CSIR and one of South Africa's most respected scientific administrators, oversaw the introduction in 1973 of the procedure which is now followed for funding government-supported scientific research in South Africa. All requests for research grants are now channelled through the office of the Scientific Adviser, who alone pleads the case for state support for science with Treasury. Major research organisations in the public sector submit estimates for the coming year for both ongoing research and new projects.

Recent practice has been to award an across-the-board increase of at least 6% in grant aid to all applicants mostly for ongoing research. As a means of exercising control on the direction of the national research effort, however, approximately 15% of the funds available have been assigned at the discretion of the Scientific Adviser to support projects recognised as being in the national interest. By this means, agricultural research, which a few years ago was automatically given more research money than it had the resources to use effectively, now receives about 32% of the total compared with nearly half four years ago. In contrast, the budget of the National Institute for Metallurgy has been growing at about 25% annually, and that of the Human Sciences Research Council by at least 15%. Overall the national R&D budget has been growing by about 11% annually.

To help him in this sensitive task, Dr Naudé made use of an independent committee to set research priorities, consisting principally of eight senior scientists. Some were retired and others were attached to industry; none had a direct interest in the research organisations seeking support.

●Until it was closed down earlier this year, the deep space tracking station operated by the CSIR at Hartebeesthoek, 40 miles from Pretoria, had earned a reputation for being one of the most reliable of NASA's worldwide network of satellite tracking facilities. Far from going out of business, the team of skilled engineers and excellent technical facilties built up during that period will now provide the basis for converting Hartebeesthoek into a monitoring station for remote sensing satellites.

The deputy president of the CSIR, Dr F. J. Hewitt, recently announced that plans are in hand to establish a line scan image processing facility service in conjunction with, initially, the Meteosat and Landsat satellites. When it becomes operational, Meteosat will play a crucial role in monitoring weather conditions over Southern Africa and the adjacent oceans. As for Landsat imagery, the new facility with its sophisticated electronic processing equipment will make it possible to collect remotely sensed data of much higher quality than is presently available from NASA in the form of transparencies of images recorded in different spectral bands.

The CSIR has become concerned that, in Southern Africa, too little advantage has so far been taken of what remote sensing satellites have to offer and, recognising that they are here to stay and bound to develop, is now to make a major effort to provide whatever facilities of hardware and software are needed to keep abreast of satellite technology. The CSIR will accept responsibility for the development of the more fundamental image processing methods, as well as for the provision of the usual infrastructural services at the tracking station. It is expected, however, that users will in time develop procedures for their own particular problems. Encouragement will also be given to sharing the facility with neighbouring territories, four of whom are already actively involved or interested in remote sensing.

Hewitt hopes that the station would be operational by August of next year, and that the sophisticated data processing and information extraction service will be available early in 1978.

Graham Baker

IN BRIEF

JET in difficulty

The hoped-for meeting of the EEC's Council of Research Ministers, provisionally scheduled for the week before Christmas, did not take place once it became clear that the Nine would again fail to agree on a site for the Joint European Torus (JET) project. The main obstacle seemed to come from France, which apparently intended to veto any proposed site other than Cadarache and suggested only CERN as an alternative. No date has been set for a future meeting. The view of the outgoing Research Commissioner Guido Brunner, that JET is "on its deathbed", is not accepted in Britain, where it is seen as an attempt to encourage an early decision.

Reprocessing developments

West Germany's recent indication that she will follow France and stop exports of nuclear reprocessing technology will not apparently cover her controversial deal with Brazil. France's own policy leaves unaffected her proposed export of a reprocessing plant to Pakistan, which is resisting pressure to cancel the deal.

Canada has meanwhile ended nuclear cooperation with Pakistan, as she did with India earlier last year, as part of a new exports policy just announced. In Britain the UK government has decided to subject plans for an oxide fuel reprocessing plant separately to a full public inquiry, but plans to expand facilities for Magnox fuel should receive an early approval. Elsewhere, Argentina has claimed she now has the wherewithal to produce nuclear weapons.

Research priorities decided

Specific areas of research in the field of gastroenterology are to be given priority by the UK Medical Research Council and the Department of Health and Social Security. Problems earmarked for the next 5 years include peptic ulcers, inflamatory bowel disease, infective hepatitis, cancer of the intestinal tract and gallstones; priority is also to be given to the study of gastrointestinal hormones, nervous control of the gut and the fundamental mechanisms of both intestinal absorption and pancreatic secretion.

Shetland's oil

KENNETH MELLANBY

THE discovery and development of North Sea oil is already having a profound economic and social effect in those parts of Scotland where it is beginning to be brought ashore. Money is pouring in unprecedented amounts into areas which have always been poor. The extraction of oil is expected to reach its peak in the 1980s, and the reserves may be exhausted before the end of the century. While I tend to share the pessimism of the recent Nobel Laureate Milton Friedman regarding the probable effects of the oil on Britain's flagging economy, I am most concerned about the ecological effects of the industrial developments, and the possibility of pollution by oil spills, breaks in the pipelines and even by continuous low level seepages on the wildlife of many parts of the Scottish coast.

One area most likely to be affected is the Shetland Islands, the most northerly group of the British Isles, where gales and high seas make the work particularly hazardous. This hitherto undeveloped region, with a population of only 19,000, will have a terminal which will deal with as much as 150 million tonnes of crude oil in a year, more than the present total imports of mainland Britain. The likely results are summarised in a small book, *The Shetland Way of Oil* (Thuleprint, Sandwick, Shetland; 1976), produced by a group of mainly local writers. They describe without undue sentiment the way in which a life-style still cherished by at least the older Shetlanders is doomed, and suggest how permanent damage to the islands could be minimised. They are particularly aware of the limited volume of the oil reserves, and the need to exploit them rapidly to repay the enormous capital invested. They wish to prevent a temporary boom declining rapidly and leaving ghost towns and derelict installations in a devastated environment.

The oil companies appear to be acting responsibly, and to be cooperating in trying to alleviate any unavoidable damage. The cynical will no doubt suggest that this is in order to placate local interests which could delay development, but nevertheless the results are promising. The UK parliament has passed the Zetland County Council Act (1974) which gives this small local government authority financial powers rather greater than those proposed for the Scottish Assembly, and they should eventually have a very large sum of money, perhaps more than a hundred million pounds, to restore damage and provide industries and amenities when the oil is exhausted. It is thus likely that only the minimum damage will be done to the landscape, to buildings and to antiquities, and that means will be found to encourage other industries to absorb those unemployed when the oil boom ends.

It is difficult to be so optimistic about wildlife, for in an operation of this size some serious pollution is almost inevitable. The good thing about the oil rush is that it has made conservationists aware of the richness of the flora and fauna of Shetland and of Scotland generally, and of their ignorance of what is actually there. It has stimulated ecological surveys by and on behalf of the Nature Conservancy Council, which show us what might be lost. Plans are being made to monitor any changes which occur during the exploitation of the oil, so that damage may be quickly assessed, even if it cannot always be prevented. Attempts are being made to find ways of minimising any damage if leaks or spills occur. Some surveys were not completed soon enough to prevent shore works being carried out in valuable wildlife areas, but some attempt to avoid these has been made. The problem of the ultimate rehabilitation of damaged habitats will also be studied.

Fishing, farming and knitting are traditional industries of Shetland. Already oil has contributed to the reduction in fish caught, though overfishing and international politics have also had their effect. High wages at the oil terminal take labour from the farms and the knitting factory. It is hoped that, when the oil is exhausted, these and other industries will be restored and developed. If there is a world energy crisis there should be an assured market for Shetland knitwear, including the Fair Isle pullovers so popular in the 1920s with the then Prince of Wales, to keep us warm when we can no longer afford to overheat our buildings.

correspondence

The scientific civil service

SIR,—Your leading article of November 18, "Don't Move", is itself guilty of throwing "the same old accusations" at the scientific civil service without any supporting evidence. The IPCS would certainly agree that the scientific civil service still lacks the right openings for mature scientists whether from within or without. It cannot, however, accept that the scientific civil servant is considerably better paid than his counterpart elsewhere; nor do scientists in the civil service feel particularly secure in their jobs at a time when cuts in public expenditure are raising real threats of redundancy.

It is of course true that industrialists frequently complain that they find it difficult to recruit in competition with the service; they are less willing to make public the details of the terms they themselves offer to scientists so that comparisons can be fairly made. Meanwhile the trend away from science continues in both the schools and the universities. The recent report from the Select Committee on Science and Technology, "University–Industry Relations", underlines the importance of reversing that trend. It will not be done by continued sniping at particular employment sectors but by improving the status of engineers and scientists in the community at large and, as the Select Committee recognises, by giving them "the opportunity of moving into the top echelons of management with as much ease as their counterparts in Germany, France or the USA and as their counterparts in Great Britain who have chosen to study law or accountancy".

Greater movement of scientists between different sectors of employment, though desirable, will not of itself solve the underlying problem of the unattractiveness of science as a career—whether in industry or the civil service.

MARGARET PLATT

Assistant General Secretary,
Institution of Professional
Civil Servants,
London WC2, UK

International contacts

SIR,—I would like to complete Professor Burhop's article ("A case of suitable treatment?", November 11) by one relevant remark. At the same time as London created obstacles in issuing British entry visas for some delegates of the World Federation of Scientific Workers' General Assembly, the former vice-president of the Federation and a long term head of its Prague Regional Secretariat, Academican Ivan Málek, was visited by two gentlemen from the Prague police, who confiscated his foreign passport, valid only for East European countries—perhaps from fears that he might try to participate in the Pugwash meeting in August in East Germany, or the London Assembly.

I fully understand Professor Burhop's indignation about the bureaucratic obstacles to realising international scientific contacts. What I don't understand is why he does not publicly condemn equally strongly the incomparably heavier fact that thousands and thousands of scientists from the USSR and Eastern European countries are extremely restricted in travelling abroad, that every single journey must be approved and depends fully on the goodwill of the authorities and political views of each applicant?

Professor Málek, a scientist with an international reputation and a member of many international organisations, committees and boards, has not been allowed to leave Czechoslovakia for over 6 years (although he is constantly being invited abroad), and only because of his disapproval of occupation of Czechoslovakia in 1968 by Soviet and "allied" armies.

FRANTIŠEK JANOUCH

Stockholm,
Sweden

USSR river diversions

SIR,—There is a disturbing aspect of the Soviet plan to divert the rivers Irtysh and Ob southward (December 2, page 390) which your correspondent does not mention. Calculations reported by Aagaard and Coachman in *Eos* (**56,** 485) suggest that by removing or reducing the low salinity layer at the surface of part of the Arctic Ocean such a scheme could allow deeper convection of the surface waters, encouraging ice to melt with perhaps a positive feedback as the albedo of the region is thereby reduced. Likely results, they suggest, "would be (1) prolonged ice-free conditions because of deep-reaching free convection . . . (2) the release of large amounts of heat from warm Atlantic water during the cold months, and (3) the elevation of quite saline water into close proximity with the sea surface".

It is not clear, of course, whether such effects should be regarded as desirable or undesirable; in the present state of the art regarding our understanding of climatic changes we can only say that repercussions of one kind or another on the general atmospheric circulation would be inevitable. Given the uncertainties involved, however, it seems most unwise to carry out the experiment.

JOHN GRIBBIN

Science Policy Research Unit,
University of Sussex,
Brighton, UK

Competition 11

Readers are invited to submit descriptions, in epigrammatic reportorial form, of the demeanour, condition or action of any of the famous scientists (past or present) participating in an imaginary general symposium. Submissions should offer some humorous association with the scientists' work, for example, "Faraday was incapacitated", "Boyle and Charles felt the meeting was 'a perfect gas' ". Closing date for entries: February 16. (Competition inspired by Charles S. Cope of Parkersburg, West Virginia.)

Competition 10. "Prehistoric camels often sit down carefully. Perhaps their joints creak. Early oiling might provide permanent relief". These memorable phrases earn Dr P. Little, of Wantage, UK, £10 as the best mnemonic of a rather disappointing bunch. They remind us that the geological epochs are Precambrian, Cambrian, Ordovician, Silurian, Devonian, Carboniferous, Permian, Triassic, Jurassic, Cretaceous, Eocene, Oligocene, Miocene, Pliocene, Pleistocene and Recent (with apologies to the Paleocene).

As we said to our accounts department, "Prepare cheque of suitable denomination. Competitor pleases the judges, conquering easily over many people's poorer reminders".

news and views

Interpreting Stonehenge

from R. J. C. Atkinson

THE formulation of astronomical interpretations of Stonehenge is becoming a minor industry with its own characteristics. These are well illustrated by a recent and a current contribution to *Nature*.

R. F. Brinckerhoff has suggested (*Nature*, **263**, 465; 1976) that selected depressions on the tops of some of the lintels were made to hold markers used by an observer, himself standing on the lintels on the opposite side of the circle, to identify significant risings of the moon. This is clearly possible under certain circumstances; but is it likely?

I think not, if only because the tops of the lintels are now so weathered as to make it impossible to distinguish artificial holes from those of natural origin. On other lintels, notably stone 152, there are many weathered holes far deeper, and no less regular in outline, than Brinckerhoff's examples, for which no astronomical explanation is possible. Furthermore, the author admits that the relevant observations could have been made only after the fall of stone 55. The date of this event is unknown; but we do know from Gowland's excavations of 1901 (*Archaeologia*, **LVIII**, 37–118; 1902) that the base of this stone was not deliberately undermined. The differential weathering of the upper and lower surfaces of the lintel which it formerly supported (stone 156) suggests that stone 55 may not have fallen until well after the end of the Early Bronze Age. There is no archaeological evidence for the continuing use of Stonehenge thereafter.

A. D. Beach (this issue of *Nature*, page 17) makes the new, ingenious, but to me equally improbable suggestion that the Aubrey Holes were used as counters for predicting tidal amplitudes by way of previous knowledge of the period of rotation of the lunar apsides. This is a more 'difficult' explanation than Hoyle's (which Beach apparently rejects) because it involves an additional generalisation from natural phenomena unobservable at Stonehenge itself.

From our present knowledge of celestial mechanics it is all too easy to impute to our prehistoric ancestors an understanding of nature which may well be ours alone. Both these papers, by concentrating exclusively on the astronomical interpretation of aspects of a monument which was surely more than an observatory (if it was ever that), lead to invalid inferences and to the posing of non-problems.

Brinckerhoff says, for instance, "No one has ever explained convincingly why it [the linteltop walk-way, so-called] had to be 16 feet high." Why indeed, except that the builders so decided within the limits of the building material available? Has anyone, for that matter, explained convincingly the height of the spire of Salisbury Cathedral? That the lintel-tops could have been used as an elevated walkway does not necessarily imply that they were.

Beach, in advancing a purely 'functional' purpose for the Aubrey Holes, dismisses the 'religious' explanation of Stonehenge I as "surely the lowest common denominator of imprecision and evasion". One wonders how he accounts for the use of Stonehenge I as a cemetery, and for the occurrence of similar cremated burials in similar rings of pits elsewhere in Neolithic Britain, for which no 'functional' purpose has ever been suggested. In fact, of course, one need look no further than many Christian churches, orientated on the sunrise either at the equinoxes or the patronal saint's day, to see that a religious purpose need not be incompatible with some elements of astronomy; nor does the incorporation of sun-dials and clocks in churches imply that they were built primarily as timepieces.

Both these papers seem to me to show an almost obsessive desire to interpret Stonehenge exclusively in 'practical' or 'scientific' terms, and to ignore the probability that it served simultaneously a number of purposes which only we would regard as separable or conflicting, and many of which, could we know them, we should find it virtually impossible to understand. The distinctions which we make between the rational and the irrational, the practical and the useless, or between religion and science, are all part of a universe of discourse which is quite inapplicable in a prehistoric context. To impose that universe of discourse on our remote ancestors is to abolish history, and to people the prehistoric past with ourselves in fancy dress. □

Metal bites metal

from Robert W. Cahn

THE recent Report of the Court of Inquiry (HMSO, London, 1975) on the disaster at Flixborough, where a caprolactam manufacturing plant exploded with grave loss of life, cited surprising evidence concerning weakening of hot stainless steel by traces of metallic zinc on the steel surface. This had not been recognised before the disaster inquiry and the special research commissioned to help in that inquiry. It appears that minute quantities of zinc, which can reach the steel either as liquid or as vapour, lead to fracture within seconds at modest stresses (5–6 kg mm^{-2}) in the temperature range 800–900 °C. Without the zinc, a stress well over 10 kg mm^{-2} would be needed in this temperature range to achieve similarly rapid fracture. This is an instance of stress-corrosion, a phenomenon which involves the mutual abetment of stress and corrosion: the corrosive agent accelerates the action of the stress and the stress enhances the corrosive attack. The importance of zinc-embrittlement in the sequence of events that led to the explosion was the central and highly disputatious issue at the Court of Inquiry; mutterings of disagreement as to the official findings may still be heard today.

Stress-corrosion by liquid metals takes place far more commonly than was recognised two decades ago: the subject has been comprehensively reviewed by M. H. Kamdar (*Prog. Mater. Sci.*, **15**, 289–374; 1973). Generally, such attack is not pronounced at or near ambient temperature, and it is thus a form of brittle fracture, enhanced by adsorption of the contaminant at the root of surface cracks. Some trace metals embrittle a variety of solid metals: thus mercury embrittles aluminium, zinc, cadmium, iron, silver, titanium and others, gallium attacks most of these metals (most spectacularly, aluminium), whereas bismuth only embrittles copper, and cadmium only iron and titanium. Mercury can claim championship status as a general trace nuisance in biology and engineering alike!

A paper by W. T. Grubb in this issue of *Nature* (Grubb, page 36) adds a further example to the growing number of instances of liquid metal embrittlement. It resembles the stainless steel/zinc syndrome in that the embrittlement is specific to high-temperature stressing and does not arise at room temperature, unlike the general run of such cases. Grubb has discovered that zircaloy-2 (a zirconium-base alloy containing 1.5 at.% tin and small amounts of iron, chromium, nickel and oxygen, which has long been used to enclose fuel elements in water-moderated nuclear reactors) is embrittled by traces of metallic cadmium—solid, liquid, or dissolved in another liquid metal—in the narrow temperature range 300–340 °C. The fracture is purely brittle in character under these circumstances and takes place by cleavage on the (hexagonal) basal plane. The report is clearly preliminary and there is as yet no information about the time during which stress must be applied to generate fracture: it is a frequent characteristic of stress-corrosion that fracture is delayed.

This finding follows the discovery, ten years ago, that iodine can cause stress-corrosion failure in zircaloys (there are several variants of the alloy) in the range 250–500 °C. J. C. Wood (*J. Nucl. Mater.*, **45**, 105; 1972) studied the matter in detail for zircaloy held at 300 °C, which is a typical reactor-operating temperature for water reactors. For adequately large stresses and surface concentrations of iodine, fracture ensued, but previous anneals to remove residual internal stresses greatly reduced its incidence. Iodine-embrittlement is of peculiar concern because iodine, a volatile element, is a major fission product and is thus created inside the fuel element during service. Other fission products, however, would be expected to 'getter', that is, neutralise any free iodine; different metals can be regarded as being in competition for the attentions of free iodine. There was, in 1972, no clear evidence that any cracks in fuel element containers had been caused by this mechanism, and I have seen no later papers to suggest that any such events had been established. Wood's paper pointed the way to a number of precautionary measures.

Cadmium-embrittlement of zircaloy might conceivably be of consequence in a nuclear reactor because cadmium is one possible constituent of neutron-absorbing control rods, and Grubb's discovery may serve to discourage the use of this particular neutron absorber.

More generally, it is now clear that liquid metal embrittlement (if we may regard iodine as an honorary metal for present purposes) falls into two clearly distinct categories: hot or creep embrittlement, and cold embrittlement. It will be the next task of background research in this field to establish the characteristics of aggressor/victim combinations that predispose a system to one of these two modes of attack. □

Economics of aggression

from John Krebs

THE idea that cultural and genetic evolution are analogous is not new: both processes consist of the survival of a few out of many possible competing entities—ideas in the former case, genes in the latter. Some anthropologists and biologists have used this obvious parallel to develop the argument that human cultural traditions, like genes, have survived because they are adaptive (Harris, *Culture, People, Nature; An Introduction to General Anthropology*, Crowell, New York, 1971; Blurton-Jones, in *Growing Points in Ethology*, Cambridge University Press, 1976). The difficult question is to decide what is meant by adaptive. In the case of genes the answer is easy: successful genes survive because their individual owners are good at surviving and reproducing (Dawkins, *The Selfish Gene*, Oxford University Press, 1976), but do cultural traditions survive for the same reason? Most discussions by ecological anthropologists have emphasised group survival as a criterion of success of cultural traditions, which goes against the intuition of an evolutionary biologist well schooled in the view that differential survival of groups is not important in genetic evolution.

Recently W. H. Durham (*Q. Rev. Biol.*, **51**, 385; 1976) has discussed the cultural evolution of traditions of intergroup warfare in man, attempting to analyse the problem in terms of costs and benefits to individuals rather than groups. In animals, aggression is almost invariably associated with competition for resources such as food and mates, and whether or not fighting evolves as a means of competition depends on the costs and benefits to individuals (see below). Resources which are too widely scattered to be economically defendable are not usually exploited by aggressive competition. Durham suggests that this may be why Eskimoes living off migrating caribou and salmon have little tradition of intergroup hostilities, while those in South West Alaska living off more reliable sources of game do have traditions of intergroup warfare. In considering group conflicts, Durham argues that the payoffs to an individual will vary with the group size. A larger group will have more chance of winning, but there are more individuals to share out whatever resource is captured through the victory. Although the details may be complex, these trade-offs will lead to an intermediate optimum group size from the point of view of an individual in the group.

Durham discusses the example of the Mundurucú of Brazil in detail. These people traditionally lived in villages of about 200 individuals and engaged in intergroup warfare, collecting heads of rival villagers as trophies. The classical anthropological interpretation of this practice is that head hunting was a

Correction

In the report "Control systems in higher plants" (*News and Views*, **264**, 214; 1976) work of Daphne J. Osborne and coworkers was incorrectly described. The last sentence of paragraph 1, page 215 should read: "The rate of germination of normally slow (low vigour) embryos is however increased by a preliminary hydration, because during this period part of the early stage of germination is achieved. The biochemical changes are maintained when the embryo is dried again, so that when next supplied with water, such embryos complete germination more quickly, or are said to be 'enhanced'. In other words, if this treatment is given to whole seeds, a higher percentage will then emerge above the soil."

Planetary alignments don't cause earthquakes

from David W. Hughes

PLANETARY tides on the Sun influence solar activity, which in turn causes an increase in the solar cosmic ray flux reaching the Earth's upper atmosphere. This triggers unusual movements of large air masses, thus effecting the Earth's rate of rotation and subsequently triggering earthquakes. This, in a nutshell, is known as the 'Jupiter effect' mainly because Jupiter exerts the largest tidal influence on the Sun (this influence is proportional to Md^{-3} where M is the planetary mass and d its distance from the Sun, so that Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, Neptune and Pluto have relative tidal effects on the Sun in the ratios of 4.1 : 97.3 : 44.2 : 1.4 : 100 : 49 : 0.09 : 0.03 : 0.001) assuming the Jovian effect to be 100.) It was first proposed by K. D. Wood (*Nature*, **240**, 91; 1972) and popularised in *The Jupiter Effect* by John Gribbin and Stephen Plagemann (Macmillan London; Walker, New York; 1974) which generated considerable discussion and also a degree of criticism, counter argument and rejoinder (*Icarus*, **26**, 257, 268, 270; 1975).

Jean Meeus, the most severe critic, pointed out that according to this interpretation of the data, planetary alignments have an undetectable effect on sunspot activity In his opinion the effect doesn't exist. But Gribbin and Plagemann's argument is that planetary alignments are important and none more so than the 1982 superconjunction when Jupiter, Saturn, Uranus and Neptune will be colinear. These superconjunctions occur about every 178.73 yr. In this time Jupiter travels 15 times round its orbit plus an extra 24°, Saturn performs six revolutions plus 24°, Uranus two revolutions plus 46° and Neptune one revolution plus 30°. Meeus points out that a period of 178.73 yr should have no special significance as Saturn, Uranus and Neptune exert a rather minor tidal influence on the Sun in comparison with, say, Venus and Earth (see above). Tides raised on the Sun by Venus, Earth and Jupiter have a period of four months and this should be the dominant factor if any interrelation exists. The temporal similarity between the 11.1-yr cycle of solar activity and the 11.86-yr orbital period of Jupiter is thought to be entirely fortuitous. Also there are two tidal bulges produced on the Sun, one at the sub-planetary point and the other diametrically opposite, so the planets don't have to be all on the same side of the Sun as was asserted by Gribbin and Plagemann. The heliocentric opposition of January 16, 1901 should have been just as effective as the forthcoming superconjunction of 1982.

Despite these arguments Gribbin and Plagemann still "see no reason yet to discard the suggestion that planetary alignments do affect sunspots, let alone the more fundamental contention that solar activity affects the Earth's rotation and therefore earthquakes."

One way to solve this disagreement is to look at earthquake data to see whether the occurrence of earthquakes has a periodicity of about 179 yr. Gribbin and Plagemann peer into the future, predicting that 1982 is going to be a year of considerable activity and a possible date for the unwelcome movement of the San Andreas fault in California.

Also addressing this problem W.-H. Ip of the Department of Applied Physics and Information Science, University of California, San Diego, does without the crystal ball and takes a more orthodox scientific approach. In a recent issue of *Icarus* (**29**, 435; 1976) he describes how Yu Shen (in *Ke Yue Shi Yan* (*Scientific Experiments*), May 1975 page 22) has divided the period between 1000 AD and the present into quiet and disturbed periods of earthquake activity using ancient records of earthquakes in Northern China. Ip finds that since 780 BC only one of the 125 recorded earthquakes with intensities corresponding to 6 on the Richter scale coincided with a heliocentric planetary alignment, this one occurring in 1624 AD. Since 1000 AD none of the eleven earthquakes with intensities of 8 has coincided. These facts really do speak out against the Jupiter effect and Californians can, one hopes, rest more easily in their beds; San Andreas will undoubtedly move some time in the future but 1982 is no more likely to be the year than any other.

---

cathartic activity promoting within-group harmony although, as Durham points out, it seems a rather extravagant method of promoting peace within the village. Instead, he suggests that the tradition is directly related to competition for a scarce resouce: game animals. The Mundurucú rely on game for high quality protein, and this is reflected in the importance of game in their religious rituals. Head hunting rituals also involved reference to game. A successful warrior was referred to as 'mother of the Peccary', referring to the fact that other village members were viewed as equivalent to game, and that obtaining a head trophy magically increased the fertility of game animals. This fits in well with Durham's interpretation that intergroup warfare is a form of individually selfish competition for game. More puzzling from the point of view of individual benefits, is the tradition that a successful warrior abstains from sexual intercourse for three rainy seasons. Not much good for individual fitness! Durham argues that the very scarcity of protein which precipitated the warfare would make procreation at that moment an unprofitable business (he doesn't say whether the whole tribe abstains), and that the warrior's payoff comes in other ways, such as exemption from future raids.

Durham's approach to interpreting cultural traditions of warfare is entertaining and makes intuitive common sense to a biologist, but whether it will really provide any predictive insight into differences between cultures rather than merely explaining after the fact, remains to be seen.

Returning to the costs and benefits of aggressive competition for food in animals, Carpenter and MacMillen, (*Science*, **194**, 639; 1976) have recently reported a quantitative study of territoriality in the Hawaiian Honeycreeper *Vestiaria coccinea*. Individuals of this species sometimes defend a feeding territory on flowering trees of the genus *Metrosideras*. Carpenter and MacMillen argue that territorial aggression will be economically advantageous as a means of securing food only if the gain in terms of increased nectar yield through excluding competitors exceeds the energy cost of territorial defence. Thus, for a given efficiency of excluding nectar thieves, territoriality will pay only if the average nectar productivity is above a certain level. (If productivity is low, no amount of exclusion of rivals will pay for itself.) At very high levels of productivity, there is so much nectar available that exclusion of rivals is not necessary, so honeycreepers should only defend food territories at intermediate levels of nectar production. By calculating the energy cost of maintenance for a territorial and non-territorial bird, as well as estimating the nectar production in each territory and the efficiency of exclusion of rivals, Carpenter and MacMillen could predict in a quantitative manner which birds should show territorial aggression, and which individuals should not. For nine out of ten birds (six territorial and four non-territorial) the behaviour was as predicted by the model. These results show how a simple cost-benefit theory can predict (as opposed to Durham's *post hoc* explanation) the occurrence of territorial competition for food in honeycreepers, although the authors suggest that an important additional factor is that the territorial birds defend more food than they need in the short term, perhaps as an insurance against hard times. ☐

Man's impact on nature

from Egon T. Degens

A Dahlem Conference on Global Chemical Cycles and their Alterations by Man was held in West Berlin on November 15–19, 1976. It was organised by Dr Silke Bernhard from whom further details may be obtained at Dahlem Konferenzen, D-1000 Berlin 33.

When man started to cut forest, burn steppe and plough land, the balanced system of air, water, life and soil was gradually disturbed. Through this type of land management, soil erosion rates quadrupled over the past 2,000 years and were borne with all their side effects by the environment, almost unnoticed by man. Industrial revolution and a growing population accelerated man's insult to nature to a point that the potential dangers are now inescapably apparent. Concerned people throughout the world are asking the now familiar questions: what is the present state of the global environment, where are we heading if increase in gross national product has higher priority than conservation, and what immediate steps are to be taken to improve the quality of the environment? At the most recent of the Dahlem Konferenzen, social and natural scientists addressed themselves again to some of these questions, though it was interesting to note that no member of the third world countries attended.

Some fourteen background papers (most of which, in my opinion, were rather catholic, indicating that we cannot yet give precise answers to global enquiries) elicited hundreds of written comments and questions. It was frustrating that only a few could be picked up in the general discussion.

Four groups addressed themselves respectively to the topics of models, modulations, and controls; fossil fuel burning and its effect on the biosphere and on sedimentary cycles; source functions: combustion products of fossil fuels, radionuclides and heat; and the resilience of the environment and of human society to changes in energy use. But it turned out that there is no way to deal reasonably with such an involved bundle of items, at least not during a five day session. Each group independently selected a few critical areas for discussion and almost identical key issues came up in the four huddles—man's impact on the global carbon, nitrogen, oxygen, phosphorous and sulphur cycles, and the interaction of C–N–O–P–S compounds with nature through these cycles.

Questions of immense importance turned out to have tremendously large uncertainties. One example may be taken—the question of whether global biomass is increasing or decreasing? Geochemists say it must increase, because they have a hard time finding another potential sink for the 'missing CO_2' in the atmosphere. This is so because, of the 4.6×10^9 tons of combusted carbon emitted every year as CO_2 into the air, only about 50% remains there; the rest apparently goes elsewhere, and it's not into the ocean. In contrast, biologists say the global biomass may remain steady or even decrease, partly as a result of excessive cutting of wood. They even believe that deforestation and the accompanying oxidation of wood and humus is a significant contributor of CO_2 to the air, and values between 1×10^9 and 5×10^9 tons of C could be annually released to the air if one uses some of the published figures

So it seems that the increase in atmospheric CO_2 is not solely due to the burning of fossil fuel but that deforestation is also an important pollutant. How can we reverse this trend? Should we plant a trillion trees, as somebody suggested? But to be realistic, there is no way out than to cut CO_2 emission to the atmosphere over the next 20 years or man will be warm but very, very sorry. Although the climate curve shows a cooling trend at present, only a minority of one-and-a-half was of the opinion that the impact of man-made CO_2 on climate is beneficial. As well as producing CO_2, fire and fossil fuel burning also release particles to the air. How do these affect global climate? Does stratospheric light-scattering by particles lower world temperatures or are the particles more efficient absorbers than scatterers and thus raise the global temperature? No opinion one way or the other was arrived at.

Equally uncertain were questions of the significance of man's perturbation of the ozone layer compared with natural perturbations. What are the quantitative effects of aerosols, N_2O, or CO? It turned out that the data base for ozone is not good. There are not only chemical but meteorological changes and not all participants shared the view that man causes the alterations noticed in the ozone layer. Are we kidding ourselves, because we ask questions on these and related issues that we cannot answer? The whole reputation of science is at stake, because in the past so much has been made of spray cans, fuel combustion and other environmental hazards caused by man's activities. The scientist's role is to bring about a change in technological approaches, which may lighten the burden on nature and at the same time help to fulfill the social needs of all the people in the world, and not just those from the developed countries. To accomplish this the scientist needs to put forward an exceptionally credible case, because the biggest inhibition of public action is disagreement among scientists.

In conclusion one of the finest results of the Dahlem Konferenz was that all participants tried to agree on the range of uncertainties, rather than being disappointed at not coming to a scientific consensus. There is a long way to go before global models of chemical cycles are universally accepted. At present the question of man's impact on sources and sinks of the biogenic elements is still up in the air.

Why marsupials can't win

from Barry Cox

One of the most intriguing problems in vertebrate evolution is the reason for the superiority of eutherians ('placentals') when competing with marsupials. Because they are so alike in their levels of morphological adaptation, it has long seemed likely that the cause lay within the fundamentally different patterns of reproductive physiology of the two groups. In an extremely interesting paper, Lillegraven (*Evolution*, **29**, 707; 1976) has recently examined this possibility.

Lillegraven commences by reviewing a number of papers by Müller, whose contributions have been largely ignored (unread?) by English-speaking workers. Marsupials are born nearly helpless, at a very early stage of development, since they have a very short period of gestation. Müller has shown that their pouch young show several features adapted to life in the pouch, such as seals to close the lips around the nipple, to protect the eyes and to plug the external auditory meatus. All these adaptations occur fleetingly in the development of eutherians, strongly suggesting that they, too, originally had a developmental history like that of living marsupials.

Although Müller herself regards the marsupials and eutherians as having developed their reproductive strategies independently from an oviparous common ancestor, Lillegraven rejects her reasons for this conclusion. His own earlier work (*Palaeont. Contribs Univ. Kansas*, **50**, 1; 1969) has shown that a comparison between the details of the structure and development of the membranes and early embryos of a didelphid marsupial and a eutherian show no features that exclude the marsupial system as phylogenetically ancestral to the eutherian system. Even the marsupial pouch is absent in such forms as the didelphid *Marsoma*, whose young swing freely from the nipples, and Lillegraven suggests that such a developmental history was present in the common ancestor of marsupials and eutherians. Such a relationship is also supported by modern palaeontological work that Müller had not considered.

Most marsupials have a gestation period of only 11–15 d. Though in some this is extended up to 38 d, this extension is not accompanied by a corresponding advance in the stage of anatomical development that has been reached at birth; instead it is accompanied by a slow-down or standstill in development. It seems as though there is a natural limitation to the amount of growth and development that can take place within the marsupial uterus, so that beyond this point the embryo must be transferred to the extrauterine nipple.

Lillegraven suggests that this limitation is imposed by the natural incompatibility between the 'foreign' foetal tissues and the tissues of the mother. Intimate relationships between these two tissues would trigger the highly efficient immune response, leading to immunological rejection by the maternal haematopoietic system. Though a placenta does develop in some marsupials, this problem restricts the duration and intimacy of relationships between foetal and maternal tissues. So the marsupial embryo can develop within the uterus only until its own food reserves in the yolk and abdomen are exhausted, and then must be born before the mother can mount a fully-fledged immunological attack.

The ability of eutherians to avoid this immunological crisis is due to the evolution of the trophoblast, which provides the major barrier between the foetal antigens and the maternal antibodies. At least one trophoblast layer always lies between foetal and maternal tissues within the placenta. The mechanism of inhibition of the maternal immune response is still uncertain, and seems to include physical separation by non-cellular trophoblasts, the development of tolerance within the mother due to transfer of materials from the placenta, and the active involvement of the trophoblast in opposing rejection of the foetus. These adaptations made it possible for the placenta to be used for respiratory and excretory exchange and for nutrition of a yolk-less embryo over a prolonged period of time. The trophoblast also transmits maternal immunoglobulins to the foetus, and is responsible for synthesis of hormones allowing prolongation of pregnancy. As a result of all these adaptations, the eutherian young can be born at an advanced stage of development, and already possessing immunity to some infections.

As Lillegraven points out, the marsupial type of development also limits that group to producing a neonate that can independently reach the nipple and survive there breathing air. This prohibits the evolution of fully aquatic marsupials, or of marsupials in which the forefeet are specialised into flippers, non-opposable fingers or single-toed hoofs. (This perhaps explains why the Australian answer to the eutherian ungulates is the kangaroo.)

At least, with living marsupials to examine and compare with their eutherian relatives, it is possible to identify such a biochemical reason for their competitive inferiority. If marsupials were extinct, palaeontologists today would be faced with an insoluble problem! ☐

Ligand binding properties of the haem group

from A. J. Thomson

DEOXYMYOGLOBIN and deoxyhaemoglobin contain the paramagnetic form of the haem group as a result of the presence of the high spin ferrous ion. It is now accepted that in this spin and oxidation state the iron sits out of the plane of the haem since it is too large to fit into the hole in the ring. On binding oxygen these proteins become diamagnetic and the iron atom drops back in the centre of the haem ring. It has been proposed, in the case of haemoglobin, that, on binding oxygen, this movement of the iron atom triggers a change in the quaternary structure of the protein which leads, in turn, to an increase in the oxygen affinity of the remaining haem residues in the protein. This mechanism is thought to be the molecular basis for the Bohr effect (Perutz, *Nature*, **228**, 726; 1970).

The nature of the oxygen–iron binding has been controversial in two respects, however. First, the stereochemistry of the iron–oxygen unit has, until recently, been much debated in the absence of good structural data. Second, the formal oxidation state of the iron atom has been in dispute.

From X-ray studies of the synthetic model compounds 'picket-fence' porphyrins ($\alpha,\alpha,\alpha,\alpha$-tetrapivalaminophenylporphyrin, TpivPP) which bind oxygen reversibly, it has been determined that the dioxygen binds iron in a bent end-on fashion with a Fe-O-O angle of 130° (Collman *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 1326; 1974). But the formal oxidation state of the iron has proved more difficult to resolve.

The problem was to distinguish between two possible states. Pauling (*Nature*, **203**, 182; 1964) has described the system as low spin ferrous iron bound to dioxygen which has become spin paired. This presumably implies little transfer of electronic charge from the iron to the dioxygen ligand. The second view first put forward by J. J. Weiss (*Nature*, **202**, 83; 1964) suggested that one electron is transferred to give a species Fe^{III}–O_2^-, the low spin ferric ion and a superoxide anion, with their electron spins anti-ferromagnetically coupled to give a diamagnetic resultant.

To probe the nature of the bound oxygen ligand and to distinguish between a superoxide ion and a neutral dioxygen the infrared stretching frequencies have been measured. This frequency drops steadily as negative charge is added (for example O_2, 1,556 cm^{-1}; O_2^-, 1,150–1,100 cm^{-1}; O_2^{2-}, 740–850 cm^{-1}). Caughey and his coworkers (*Biochem. biophys. Res. Commun.*, **55**, 91; 1973; *Biochem. biophys. Res. Commun.*, **58**, 166; 1974) in pioneering experiments succeeded in measuring the dioxygen stretching frequencies in both oxymyoglobin and haemoglobin, obtaining values of 1,103 and 1,107 cm^{-1} respectively. On substitution with the isotopically-labelled species $^{18}O_2$ shifts to 1,065 cm^{-1} were seen in both cases, adequately confirming the assignment of the bands. Although these values clearly lie in the superoxide range Caughey and his collaborators do not favour a formulation as ferric superoxide, rather they prefer to talk of strong covalent bonding between the iron atom and dioxygen. Initial attempts to measure the oxygen stretching frequency in the model Fe-TpivPP compounds produced a value of 1,385 cm^{-1} (Collman *et al.*, *J. Am. chem. Soc.*, **96**, 6522; 1974). It is now known, however, that this result was an artefact caused by an unknown impurity in a KBr disk. Recent measurements place the value at 1,163 cm^{-1} in a Fe(TpivPP)(NTrIm)O_2 model and 1,159 cm^{-1} in Fe(TpivPP)(NMeIm)O_2, where NTrIm is 1-tritylimidazole and NMeIm is 1-methylimidazole. Isotope shifts on substitution with $^{18}O_2$ are used to confirm assignments (Collman *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **73**, 3333;

1976). This revision brings the model compound values close to the haemoprotein values, all now lying within the superoxide range.

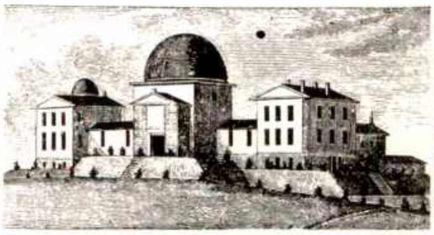
A comparison can usefully be made with a range of cobalt–porphyrin derivatives which also bind oxygen reversibly. Caughey and Maxwell (*Biochem. biophys. Res. Commun.*, **60,** 1309; 1974) have shown that the dioxygen stretching frequency in the cobalt(II)porphyrin analogue of haemoglobin is 1,105 cm^{-1}. Now the recent report from Collman, *et al.*, puts values of 1,153 and 1,150 cm^{-1} to the cobalt 'picket-fence' analogues with different axial bases. The change of the metal ion has not significantly altered the stretching frequency. But since the cobalt analogues possess one more d-electron than the iron compounds an EPR signal can be obtained. It was shown by Hoffman and Petering (*Proc. natn. Acad. Sci. U.S.A.*, **67,** 637; 1970) that the cobalt–oxygen adduct gives a signal with no cobalt nuclear hyperfine structure visible. They therefore concluded that the odd electron is largely on the dioxygen and that the formulation Co(III)–O_2^- is the most appropriate. In view of the similarities between the stretching frequencies of the dioxygen when bound to cobalt or iron model porphyrins and haemoproteins it is difficult to resist the conclusion that J. J. Weiss was correct in 1964.

In their oxygen-binding properties the picket fence porphyins model the haemoproteins well. An interesting difference arises, however, in their very different affinities for the ligand carbon monoxide. The picket fence model binds CO irreversibly whereas the oxygen-carrying haemoproteins have considerably lower binding affinities which vary in the different mutant forms, in other words, as a function of protein structure. Collman *et al.* have now pointed out that the CO stretching frequency drops as the CO affinity of the haem group drops. It is suggested that the CO affinity in the protein is lowered as a result of the steric constraints of the haem pocket's causing the Fe–CO group to become bent and the iron–carbonyl bond to be weakened. Because the Fe–O–O structure is intrinsically bent its affinity is not correspondingly reduced. This ability to discriminate against CO binding may be of crucial importance since the biological catabolism of haemoproteins is a primary endogenous source of CO. The authors conclude that poisoning by CO of both haemoglobin and myoglobin would be considerably greater if the CO ligand were not forced to tilt.

It is admitted, however, that it may be an oversimplification to ascribe all the differences between CO and O_2 binding to the steric constraints of the haem pocket. In planar systems with trans-axial ligands there is an appreciable electronic affect transmitted across the metal plane. This was nicely shown in model studies using cyano-cobalamin, which contains the cobalt(III)-corrin ring system. The infrared stretching frequency of the bound CN$^-$ ligand was measured as a function of the ligand *trans* to it (Firth *et al.*, *J. Chem. Soc. A*, 2428; 1968). There is a perfect correlation between the binding constant of the cyanide group and its infrared frequency; the frequency drops as the binding constant drops. The decrease in affinity for cyanide is brought about by a change in the *trans*-axial ligand and can only be due to an electronic effect transmitted by way of the metal ion. Now it is known that in the haem models Fe(deuteroporphyrin) (2Me-Im) the CO is bound 200 times less well than in Fe (deuteroporphyrin) (Im). 2-methylimidazole (2Me-Im) is a sterically hindered base which cannot approach the porphyrin plane closely (Rougee and Brault, *Biochemistry*, **14,** 4100; 1975).

Thus there is also a pronounced electronic *trans* effect in the iron–porphyrin system. Another function of the protein in the oxygen-carrying proteins could well be to control the distance between the haem plane and the bound histidine residue, thereby affecting affinities for *trans* ligands. It is not yet known whether such control will affect the affinities for both CO and oxygen in a parallel manner. ☐

A hundred years ago



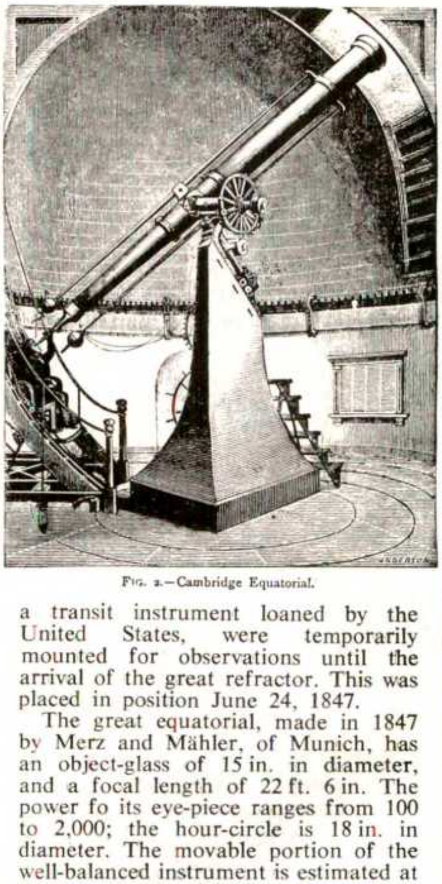


Fig. 2.—Cambridge Equatorial.

CAMBRIDGE (U.S.) OBERVATORY

A look into the earlier annals of the observatory of Harvard repays the inquirer at the outset by revealing the interest in astronomical pursuits which was felt in the old Bay State many years before the founding of an observatory was practicable in the United States. In 1761 the *Province* sloop was fitted out at the public expense to convey a Harvard professor, Winthrop, to Newfoundland, to observe the transit of Venus of that year; and in the troublous times of 1780 the old "Board of War" fitted out the *Lincoln* galley to convey Prof. Williams and a party of students to Penobscot to observe a solar eclipse. At so early a day was New England disposed to encourage scientific observations.

A new issue now arose. The sudden appearance of the splendid comet of 1843 was, happily, the occasion of final success in the founding of the present institution. Cambridge was immediately appealed to for information about this strange comet. But the observers had no parallactic instruments or micrometers of the least value for its observation. While they were endeavouring to obtain data to compute the comet's orbit, a meeting of citizens was held, under the sanction of the American Academy, to take measures for procuring a first-class equatorial; the needed amount of $20,000 for the instrument was contributed in Boston, Salem, New Bedford, and Nantucket. The equatorial was ordered from Merz and Mähler, of Munich, and Harvard determined to erect a new observatory. The location selected was 80 ft. above tide-water, and 50 ft. above the plain where the soil was found favourable for the stability of piers for the instruments. In 1844 the buildings were occupied, and an equatorial of 44 in. focal length and 2½ in. aperture, and a transit instrument loaned by the United States, were temporarily mounted for observations until the arrival of the great refractor. This was placed in position June 24, 1847.

The great equatorial, made in 1847 by Merz and Mähler, of Munich, has an object-glass of 15 in. in diameter, and a focal length of 22 ft. 6 in. The power fo its eye-piece ranges from 100 to 2,000; the hour-circle is 18 in. in diameter. The movable portion of the well-balanced instrument is estimated at three tons. Its original cost was about $20,000. The sidereal motion given to this telescope is now secured by clock-work from Alvan Clark, which is spoken of by the observers as the only known "driving-clock working with perfect steadiness." The telescope rests on a central granite pier, in constructing which 500 tons of granite were used. It is 40 ft. high, and rests on a wide foundation of grouting 26 ft. below the ground surface. Upon the top of the pier is laid a circular cap-stone 10 ft. in diameter, on which is the granite block, 10 ft. high, bearing the metallic bed-plate. This instrument is in the central "Sears Tower."

Stonehenge I and lunar dynamics

A. D. Beach

P.O. Box 2225, Auckland, New Zealand

The concept of Stonehenge I as an accurate predictor of eclipses can be criticised on the grounds of inadequate short-term precision, unnecessarily good long-term tracking of the lunar nodes, and irrelevance to cultural needs. A more practical application of the astronomical characteristics of the structure is that of lunar apogee tracking, which would allow prediction of minimum tidal disturbance to cultural communication across the North Sea and English Channel.

FOLLOWING Hawkins[1] numerical analyses and discussion of the alignments between components of the Stonehenge monument on Salisbury Plain, England, (described by Atkinson[2]) the succeeding decade of investigation has further emphasised the dichotomy of viewpoints between the astronomers and the archaeologists. Some of the original deductions of Hawkins have been strongly criticised by both groups[3–6], but the work of Hoyle[7] and of Newham[8] has extended other aspects and shown that Stonehenge I, the earliest phase of the megalith, could have been used as a universal eclipse predictor, independently of any eclipse cycle.

Operation of the device in this mode would have been simple, but the sophisticated intellectual reasoning needed to design the system conflicts to a high degree with the otherwise satisfactory archaeological picture of Britain as having a technologically primitive agricultural economy. Although now endorsing an astronomy-oriented content in the Stonehenge structure, most archaeologists resile from the 'eclipse computer' concept *per se*, because of this incompatibility, preferring religious connotations to explain the interest in the Sun and Moon[6].

Stonehenge I

The concensus of opinion is that the initial phase of Stonehenge consisted of:

(1) The raised bank and quarry/ditch (both originally about 2 m from datum).

(2) The circle of 56 pits, named 'Aubrey holes' (A holes), filled in shortly after their original excavation. Erosion of the surface since the construction date makes their original form doubtful, but it is noteworthy that the excavated material, replaced in the hole, would exceed the pit volume and form a chalk mound, an ideal quasi-permanent marker of high visibility in twilight conditions. The name Aubrey holes may be rather misleading.

(3) The primary alignment, represented by a line from the central point to the heelstone[9], with its associated quadruplet of equally spaced 'A' postholes. This is not the axis, which is of phase II/III origin.

(4) The 'causeway' postholes at the 'entrance'[8].

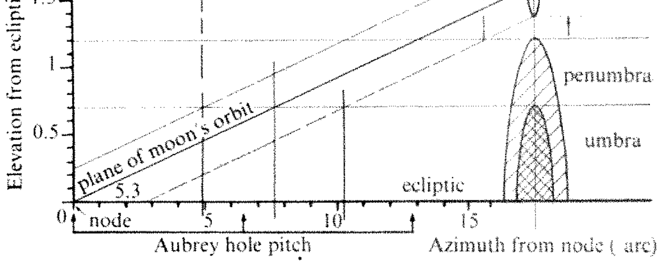
(5) The *locations* of the 'station stones'. The actual station stones appear to have phase III characteristics, but the locations are deemed significant, and relevant to phase I because of their near-rectangular geometry resulting from the choice of latitude for the Stonehenge site[8].

Angular resolution and the Aubrey holes

It is a weak point in the astronomical argument that, as an eclipse predictor, Stonehenge I is embarrassingly comprehensive, potentially capable of predicting all eclipses, when only about half could be observed from a single location. A much more stringent criticism, however, is the inadequacy of the moment-to-moment accuracy of the tracker markers in the 56-step 'plan position indicator' scheme of Hoyle. An unsynchronised incremental movement of 6.43° in each of three markers, Sun, Moon, and node-pair, gives a potential average angular error of $\sqrt{3}$ Aubrey holes, or more than 11° arc. The Lunar eclipse prediction requirement can be assessed from Fig. 1 and it can be seen that an 11° error would be sufficient completely to miss even an umbral eclipse if it were tangential. Moreover, solar eclipses require better than twice the resolution needed for lunar eclipse prediction. At any time in the operation of Stonehenge I, the average error could have been halved by a simple doubling of the number of Aubrey holes and of the rates of marker movement, so it is reasonable to suspect that eclipse prediction was not the prime purpose of the Stonehenge I Aubrey hole array.

The number 56 of Aubrey holes is of critical importance in the circumstantial evidence for the astronomical case. Fifty-six is very close to three times the nodal regression period in years (55.835), and has led most investigators to accept the relevance of the extraordinary accuracy of node tracking implicit in this close match. Node markers moved around the Aubrey circle at three Aubrey holes per year (A.H. yr^{-1} hereafter) relative to a fixed 'equinox', accumulate an error of only one Aubrey hole in more than a century, and can thus easily be reset by 93 yr periodic

Fig. 1 The angular relationships between mean lunar angular diameter and the Earth's umbra and penumbra, in a lunar eclipse situation. The incremental angular resolution of the Aubrey hole array would not be satisfactory for a definitive prediction of an eclipse, if the average error were $\sqrt{3}$ Aubrey holes (see text).



recalibration observations of maximum northerly midwinter full moonrise azimuth. The figure of 93 yr is arrived at because five times the nodal regression period is 93.06 yr, adequately close to an integral number of midwinter solstices.

The logic of this interpretation of the significance of the number 56, however, is suspect. The argument of Hoyle is that the most northerly azimuth of midwinter fullmoonrise (the peak of the nodal cycle), was determined by interpolation, using the A posts (and thus achieving independence from a rather infrequent coincidence of fullmoonrise with winter solstice) primarily for the purpose of determining the date of that event, the reset moment of the nodes markers. But it is a simple fact that the cancellation of any accumulated error in the nodes markers could have been achieved many times per decade, by observation of lunar eclipses. Any total lunar eclipse of long duration would automatically define the near-zero angular displacement of the nodes from the Sun–Earth–full moon axis to a precision rather superior to that achievable by deducing the date of maximum northerly virtual fullmoonrise (abbreviated hereafter to MNVF).

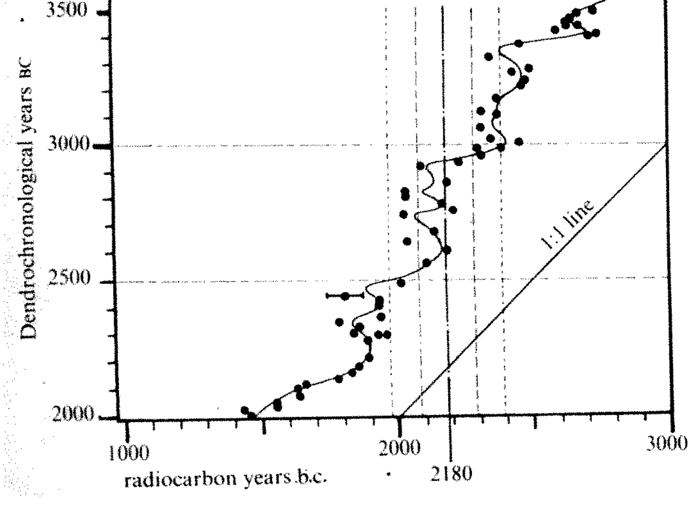
The concept of the interpolation technique is valid, provides an elegant solution to the use of the A postholes, and is highly relevant to the argument that follows, but the task assigned to it by Hoyle cannot be considered logically justified.

The new dating

The radiocarbon dating revolution within archaeology has caused a considerable reassessment of the process of cultural diffusion from Western Asia to Europe, and of the relation of Stonehenge to the Wessex culture. Following the publication by Suess[10] of his dendrochronologically-based calibration chart for radiocarbon samples, Stonehenge I in particular has become very difficult to assess. The most relevant sample, I-2328, chosen as representing the earliest construction phase, is from the antler pick found 3 in above the bottom of the outer ditch at 6 ft depth, in the primary silt[9]. Isotopes Inc. dated this at 2180±105 b.c.

The present position is summarised in Fig. 2. Because of the 'staircase' curve, the new calibration would give essentially the same radiocarbon date for samples of real origin dates between about 2500 BC and 3000 BC. (The reality of the Suess calibration curve retrogressions has of course been questioned, but the larger ones, such as those in Fig. 2, do seem to be caused by an actual fluctuation in the ^{14}C levels of the period[11,12].) Further sample dating is urgently needed.

Fig. 2 The Suess dendrochronologically-based radiocarbon calibration curve for the calendrical interval 2000–3500 BC (adapted from ref. 10), with the radiocarbon age data for Stonehenge I sample I-2328 (2180±105 BC) superimposed. The vertical dashed lines define the normal distribution confidence levels of 68% and 95%. Suess' typical dating uncertainty limits are given for one of his points; the limits for the other points have been omitted for clarity.



The anomaly of Stonehenge I is now better realised. The uncertainty of dating does not obscure the probability that this geometrically established structure predates the main building phase of the Egyptian pyramids, and that it may have been contemporary with the proto-literate Sumerians[13].

An important outcome of the new dating is the modification now necessary to the values of parameters used to calculate the positions of some astronomical entities. It will be seen that the date regime 3000–2500 BC is of great significance to an improved understanding of Stonehenge I.

Static geometry and dynamical astronomy

In the past the emphasis has been on the midsummer sunrise phenomena at Stonehenge. For this to have obscured for so long the much better match of the structural geometry to the midwinter moonrise phenomena, is rather surprising. The entrance includes the range of moonrise azimuths from that represented by the heelstone, to the MNVF azimuth, and is asymmetric with respect to the avenue. This same range of azimuths covers the causeway postholes, investigated by Newham, all of which are northward of the heelstone azimuth and which have three ranks terminating close to the MNVF azimuth.

This emphasis on the extreme northerly azimuth of moonrise is evidently very important to investigations of the motivation behind Stonehenge I, and now that a more definitive range of radiocarbon dates has been derived for this part of the structure, it is relevant to attempt the determination of the actual solsticial moonrise azimuths for that period, so as to achieve a greater understanding of the designer's motivation.

I have used the polynomial expressions for the angular positions of features of the lunar orbit, given in the explanatory supplement to *The Astronomical Ephemeris* (HMSO, annually), to examine the moonrise azimuth situation in the period 3500–2000 BC. When using these expressions it must be remembered that the imprecisely known secular acceleration of the Moon leads to some uncertainty regarding the lunar longitude at times remote from the AD 1900 epoch, but it is considered that the expressions for the lunar node and perigee are accurate to a few degrees for periods up to 100 Julian centuries (Her Majesty's Nautical Almanac Office, personal communication). The parameter T (Julian centuries) is common to all the polynomial expressions, and its value for each winter solstice of the relevant years can be determined by solving for T the solar longitude expression when the longitude is defined at 270°. The accurate value for T can then be inserted into the expressions for obliquity of the ecliptic, and for the longitudes of the Moon's ascending node and perigee.

The spherical trigonometry used to determine from these parameters the azimuth of virtual moonrise has been described elsewhere[7] (moonrise is defined as the tangency of the Moon's lower limb to the horizon). Assuming the present-day value for the eccentricity of the lunar orbit, and that the atmospheric conditions were 1002 mbar and 10 °C, as used by Hawkins[1], then with the measured value of 0.60° for the elevation of the relevant portion of the Stonehenge horizon, the virtual moonrise azimuth can be determined to a high accuracy (typical uncertainty for ± 50 mbar in atmospheric pressure, for example, would be ± 0.05° arc in azimuth).

Coincidence of azimuths

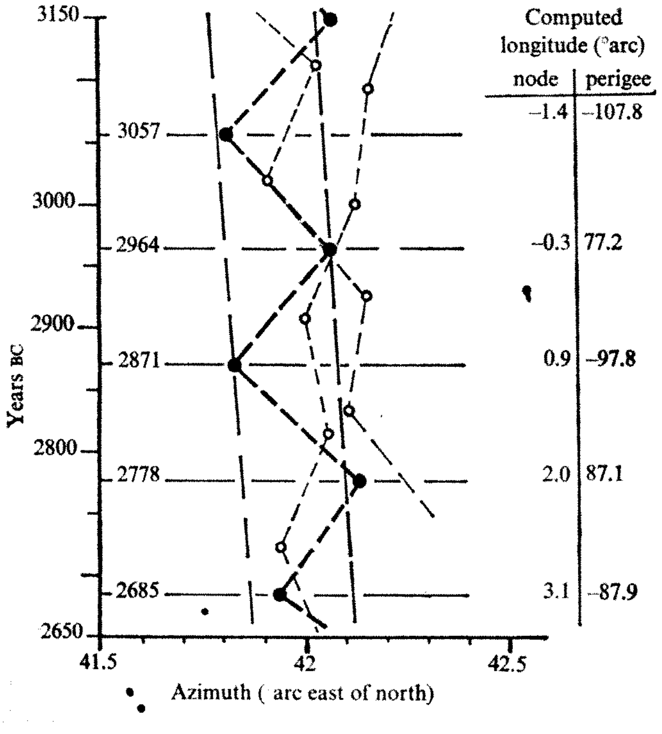
The conditions for extreme northerly virtual fullmoonrise are that the line of nodes be exactly in quadrature at the winter solstice (the longitude of the ascending node being zero), and that apogee be at the virtual fullmoon point, for minimum horizontal parallax. The first criterion alone is a moderately rare phenomenon, even when allowing a few degrees of longitude tolerance. Within the arbitrary limits of ± 1 A.H. of longitude, eligible coincidences occur approximately three times every 93 yr. Because it is at this time in Hoyle's scheme, that the nodes marker-pair is checked for 'longitude' accuracy, however, it is highly significant that the normal incremental angular resolution of 1 A.H. is much improved by a knowledge of the temporal mismatch between nodal quadrature and winter solstice.

For the second criterion to coincide with the first is rather more rare. To an arbitrary limit of 2 Aubrey holes of longitude accuracy (for a hypothetical apogee marker), coincidence occurs at intervals of about 1247 yr (67 cycles of nodal regression and 141 cycles of apogee precession).

A computer programmed to perform the necessary search, showed that at the winter solstice of 2871 BC ($T = -47.699$ Julian centuries from AD 1900), the ascending node of the lunar orbit had a longitude of about 1°, and apogee was about 7.8° from the virtual full moon point. Figure 3 shows the sequence of MNVF azimuths between 3250 BC and 2400 BC. Of particular interest is the sequence of apogee MNVF azimuths for the years 3057, 2871 and 2685 BC. At 41.8°, 41.83° and 41.88°, they are very close to the extreme limiting azimuths possible at those times.

It is remarkable that the causeway postholes investigated by Newham[8] contain three ranks terminating at azimuths which he measured at 41.8°, 41.9° and 41.9°.

Fig. 3 Computed azimuths of virtual fullmoonrisings at winter solstice, in the calendar date regime 2650 BC to 3150 BC, as seen on the NE horizon of Stonehenge, when the ascending node of the lunar orbit was less than one Aubrey hole pitch from the equinox. The pair of nearly vertical dashed lines are the azimuth limits for apogee and perigee when the longitude of the ascending node is zero. The rare sequence of nearly perfect apogee and perigee azimuths, which occurred in the Stonehenge I period, is shown emphasised.



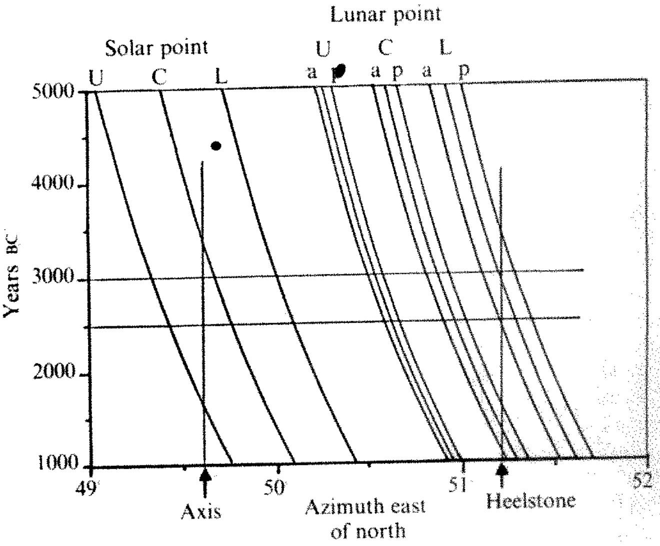


Fig. 4 The heelstone azimuth. The curves show the rising azimuths for the upper, (U), and lower, (L), limbs, and for the geometrical centre, (C), at winter solstice and nodal syzygy for the Moon, and at summer solstice for the Sun. Apogee and perigee displacements are given for the Moon. The general shift of all azimuths with time is due to the changing obliquity of the ecliptic. The 2500 and 3000 BC time lines facilitate correlation with Fig. 2. The axis azimuth is approximate only, but the heelstone azimuth was accurately measured by Hawkins[1], as 51.222.° At the winter solstice of the year 2857 BC, the ascending node of the lunar orbit had a computed longitutude of 90.0° (syzygy) and the azimuth of fullmoonrise for the lower point was computed to be 51.28°.

Such a close coincidence encouraged me to pursue the investigation and examine the remaining feature of Stonehenge I at the other extreme of the entrance azimuths, the heelstone. Robinson[9] had pointed out that the heelstone was a better marker of the node at winter solsticial syzygy than it was of midsummer sunrise, and my computations bear this out to a remarkable degree. Figure 4 demonstrates the striking match of the heelstone azimuth to that of the moonrise azimuth for nodal syzygy in the date regime centred on 3000 BC (again for lower limb tangent to the horizon).

For the sinusoidal function of winter solsticial moonrise azimuth to be marked in the Stonehenge I structure at no less than four points (the rare triple extreme event and the 'crossover' point) is prime evidence for a knowledge of the existence and of the accurate position of the lunar node, that can be described only as astonishing in its precision.

Moreover, the marking of the apogee MNVF azimuths and the omission of the perigee equivalents has some interesting connotations.

Apogee tracking

In Hoyle's scheme, the most accurate tracking is that of the nodes, which in 2871 BC accumulated an error of 1 A.H. every 111 yr (when moved at 3 A.H. yr^{-1} relative to a fixed 'equinox'). This figure is arrived at by differentiating the polynomial expression for the longitude of the lunar node, with respect to time, and inserting the appropriate value of T into the resulting expression, to obtain the real regression rate (18.6107 tropical years per rev.) and then taking the reciprocal of the difference between the ideal Aubrey hole marker rate (3.00902 A.H. yr^{-1}) and the prescribed rate.

Remarkable though this accuracy (or coincidence) seems, it is outweighed by an even more accurate relationship. Performing the same calculation for an apogee marker, the precession period is found to be 8.84516

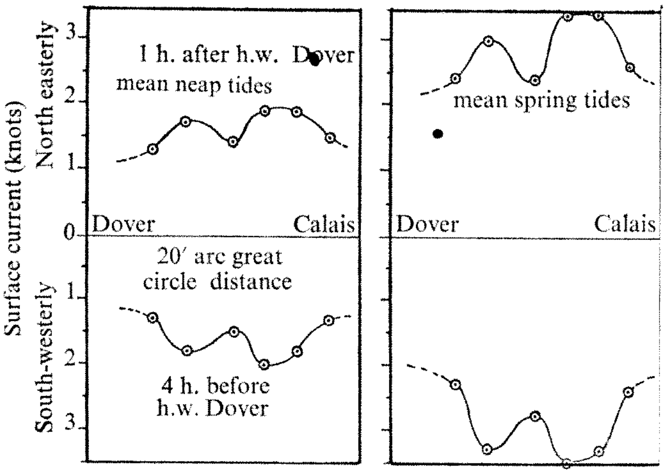

Fig. 5 Present-day surface currents in the Dover Strait. By rowboat, at 2.5 knots, the 20′ arc surface traverse would require 8 h if there were no tidal disturbance. For a daylight journey, from embarkation to landfall, the most suitable tidal conditions would be those at apogee neaps, when the peak surface current may be expected to be about 13% less than than at mean neaps.

tropical years, the ideal A.H. tracking rate 6.33115 yr^{-1}, and the error accumulation rate, for a marker moved at 6.33333 A.H. yr^{-1} (6, 6, and 7 Aubrey holes in a repeating triennial sequence), 1 Aubrey hole every 458 yr. Only for 56 Aubrey holes does this combined accuracy exist for both nodes and apsides trackers.

Such circumstantial evidence has been the basis for all previous astronomical interpretations of Stonehenge, especially the eclipse predictor aspect mentioned above, but it is also true that the presumed cultural motivation for Stonehenge I has been specified to match these hypotheses. Since eclipses could have served no practical purpose in what was essentially a subsistence farming economy, the motivation has been stated as 'religious'; surely the lowest common denominator of imprecision and evasion.

The hypothesis discussed below is an attempt to demonstrate a strong cultural motivation for the origin of Stonehenge I, in which the observations of natural phenomena are logically extended, and lead to the analogue device which has for so long puzzled a multitude of investigators. The only assumption that need be made is that the spectrum of intelligence present in the indigenous population of Neolithic Britain and Europe, was essentially the same as it is today, surely an acceptable criterion in view of the precision of azimuthal delimiting described above.

The relevance of tides

Thom[14,15] has suggested that the background to the north British megaliths could have been an interest in the lunar influence of tides, but these structures he dated from astronomical considerations, to about 1750 BC. Nevertheless, there may be a connection with the 1,000 yr older Stonehenge I lunar observatory.

The pre-Wessex south British cultures seem to have been culturally isolated from mainland Europe during the Stonehenge I period. A major factor contributing to this situation may have been the difficulty of traversing the strongly tidal English Channel, Dover Straits, and North Sea. To the operator of any surface craft whose speed is limited by the use of sails or oars, the need for tidal prediction is obvious, even today. In 2750 BC with sea levels averaging 4 m lower than at present[16], and tidal currents over the continental shelf therefore appreciably more severe, and with the surface craft operational qualities perhaps less adequate than those of modern craft, the situation could have been even more relevant.

Figure 5 has been derived from a standard tidal stream atlas[17], and shows the present-day strength of the tidal streams in the Dover Strait. The high values of stream velocity over the entire width of the Strait emphasise the need for small craft to choose conditions of minimum tidal disturbance for a safe and reliable crossing.

Consideration of the criteria determining tidal phenomena shows that the maximum tide-raising force exists when the following priority-ordered conditions are met simultaneously: (1) Lunar phase 'New' or 'Full', with an eclipse as the extreme event; (2) Moon at perigee; (3) Earth at perihelion (2 and 3 because of the inverse-cube law of tide-raising force with separation distance); (4) Earth at equinox, for peak semi-diurnal tide; (5) Line of nodes in syzygy. Condition (1) is virtually the defining parameter of 'spring tide', with (2) as a major modulator of the effect, having a force ratio, perigee–apogee, of 1.39. The force-ratio for (3) is 1.126. Condition (4) is important since the Atlantic Ocean responds mainly to the semi-diurnal tide-raising force[18]. Least important is (5), serving only to reduce to zero the very small effect of a few degrees separation of the solar and lunar radius vectors.

With the lunar perigee–apogee situation known to have existed at Stonehenge in the period 3057–2685 BC, Neolithic observers had a significant opportunity to notice that the difference in spring tide range correlated with the observed change in MNVF azimuth, and thus to link these two phenomena. But for this to be fortuitous is of far too low a probability to be taken seriously. Some link between the variation in tide range and the lunar motion, must have been suspected for the motivation to be established to carry out detailed observations as evidently occurred at Stonehenge.

The first order effect of condition 1 is obvious enough, but the modulation due to (2) might seem rather more difficult to observe. There is however, a curious near-commensurability in the relevant intervals which immensely aids observation. Expressed in terms of the lunar motion:

Synodic month (phase to phase):

$$29.53089\ \text{d}\times 14=413.428\ \text{d}$$

Anomalistic month (perigee to perigee):

$$27.554551\ \text{d}\times 15=413.318\ \text{d}$$

$$\text{Difference}=0.11\ \text{d}$$

Hence the perigee/apogee axis moves through one lunar phase cycle in slightly less than a 14-lunation period. In terms of the tide-raising force, therefore, there is evidently a periodic modulation in the range of the Spring tide, and of the strength of the tidal currents, occurring cyclically over 14 lunations, with maxima at 7-lunation intervals, alternately at New and Full Moon. Similarly the neap tide effects vary with the same periodicity, with minima at every seventh first and third quarters.

If this 14-lunation periodic effect had been exact, then possibly no problem would have existed, but the slow phase shift between the incommensurable periods of lunar phase change and perigee precession would destroy the relationship in less than a century. The motivation to examine, in a more detailed fashion, the motion of the Moon, may well have stemmed from this inexactitude.

Calibration of the perigee–apogee markers

Numerical coincidence may, once again, be cited, but it is a fact that $56=4\times 14$. The convenience of the Aubrey hole number allows the existence of a perigee/apogee marker-pair which could be moved at the simple prescription rate of 4 A.H. per lunation relative to the Sun marker. In Hoyle's tracking scheme, the Sun marker moves at the observationally corrected rate of 1 A.H. per 6.52218 d or 4.527716 A.H. per lunation. The net perigee marker movement rate is thus 0.527716 A.H. per lunation in the same direction as the Sun and Moon markers. This is equal to 6.5269 A.H. yr^{-1}, differing from the computed ideal rate of 6.3309 A.H. yr^{-1} by 0.1960 A.H. yr^{-1}.

If the Apogee marker were set into operation at the winter solstice of 3057 BC or 2871 BC, at this empirically determined rate, then 93 years later the perigee marker would be 18 Aubrey holes ahead of its proper position, after 10½ revolutions around the Aubrey circle. To assess the correct rate should have been a simple task to the geometers who designed the Stonehenge I structure.

Location and planning

Why Stonehenge? Or rather, why Salisbury Plain? As a site for a tide predictor it could hardly have been selected much further from the coastlines of what is now Southern England. But Stonehenge is not misplaced if consideration is given to the observational requirements. These may be listed as:

(1) Elevated plateau for an unobstructed view of the horizon.
(2) Level and treeless horizon, at least over the appropriate range of azimuths, so that the simplest relationship exists in the azimuth sequence.
(3) Horizon slightly elevated and not too distant, to avoid the worst effects of atmospheric refraction and absorption.
(4) Nearby land sloping slightly downwards away from the observing site to drain away winter groundmist, again at least over the appropriate azimuths.
(5) Not in the vicinity of a seacoast or of a large body of water, to avoid seamist or fog in winter.

That the Stonehenge site meets all these conditions may be an indication of the geographical coverage available to the designers. The Station Stones also indicate this, if their near-rectangular geometrical relationship really is due to a choice of latitude. The cultural aspects of these points have not been adequately discussed: the implication is of a cultural homogeneity of hitherto unsuspected extent.

The planning of the measurements and the choice of site certainly seem to have been justified by the practical execution of the observations. It now seems very likely that the causeway postholes represent, as Newham suggested, a sequence of measurements now that can be seen to culminate in the apogee moonrise azimuths of the winter solstices of 3057, 2871 and 2685 BC. The chance of accidental coincidence of azimuth, of the triple extreme astronomical event, and of the terminal postholes is slender indeed.

The ability to track such an elusive entity as the lunar apogee can be logically derived from the circumstantial evidence of Stonehenge I, as has been argued earlier. The later argument, of tidal prediction, is wholly speculative, being on a par with the eclipse prediction hypotheses, but contains the redeeming feature of practical motivation, unconnected with 'religion'. Moreover, the practical application is of a lower order of intellectual achievement than is the prodigious feat of designing and actually using a Neolithic lunar observatory. It is the latter for which we have evidence, and speculation on its purpose seems to me valid if there is required no great extension of the talents so clearly evident, five millennia after their application.

Mantle origin of Cordilleran granites

G. C. Brown
Geophysics Department, Liverpool University, Liverpool L69 3BX, UK

'Granite' batholiths of recent destructive margins have strontium isotopes inconsistent with crustal fusion. Associated enormous crustal thicknesses are produced without compressive shortening. These features necessitate accretion by vertical addition of predominantly mantle-derived calcalkaline intrusive and extrusive magmas.

ONE of the more controversial debates in contemporary earth science concerns the origin of granitic rocks, particularly those batholithic volumes characteristic of modern ocean–continent convergence zones. For some time the consensus of opinion was swayed by the weight of experimental evidence[1–3], accumulated over two decades, which shows that batholiths are derivable by partial melting at crustal pressures provided an ample source of metasediments is available. The overlap of granite melting conditions with granulite facies metamorphism of lower crustal regions is consistent with the extraction of such partial melts from their residua[4] leading to the two-layer crust typical of continents.

Theories of granite melting in the crust have been modified to explain the observed time–composition relations in batholiths which characteristically vary from early intermediate through to acid members of the granite family at later stages[5–7]. Detailed mapping in the Mesozoic and Cenozoic batholiths of Peru[8] has shown that minor cycles of this type, due to high level fractionation[9], are superimposed on a major cycle of primary differentiation starting with gabbro and terminating some 80 Myr later with adamellite. Considering the time span occupied by this primary cycle (note also California[6,10] and Alaska[11]) it is preferable to invoke a mechanism whereby separate batches of magma are generated by partial melting at successively higher crustal levels[12]. This conclusion follows from the crustal pressure experimental data: more acidic (and hydrous) melts are produced at lower pressures and temperatures. In the context of crustal melting, the most plausible way of having the highest melting temperatures

R391

recorded by the earliest intrusives is to suppose that crust–mantle interaction occurs at deep levels. Thus the origin of Cordilleran granites became linked to mantle processes (see also refs 7, 13–15) and I suggested[12] that rising andesitic magmas, generated within or above a subduction zone and either underplating or penetrating the crust, supplied essential heat and volatiles necessary to initiate granite melting at the deepest crustal levels. Once initiated, the granite cycle would be perpetuated with progressively more acidic contributions from shallower levels as the crust warms through from the base. Through this rather intimate association of potentially extrusive and intrusive magmas the time and space patterns of the latter are reconcilable, with a crustal anatectic origin. It follows that this evidence, and that involving time–composition relations, does not necessarily imply a mantle source for Cordilleran granite magmas which is where the strength of earlier arguments of this nature lay (ref. 14, for example). However, as field data and geochemical–isotopic observations have become more numerous, there have emerged two other persuasive lines of reasoning, considered below, which apparently place granite magma genesis at mantle depths.

The fractionation of large volumes of basic magma to produce granite batholith magmas[13] is not a popular theory because of the proportionately larger volumes of intermediate fractionates which are not found. Instead, these days the question we ask is whether relatively small percentages of basic to ultrabasic mantle melting or rather greater degrees of intermediate composition lower crust melting is responsible for granite magmatism.

Evidence from strontium isotope ratios

First we have the low initial strontium isotope ratios (^{87}Sr/^{86}Sr) which are emerging as a ubiquitous feature of Cordilleran granites. The values measured on a wide range of Western American granites range from 0.703 to 0.708 with the majority around 0.706 (refs 16–20), and values have been observed to increase with decreasing age in some Peruvian intrusives[21]. These ratios are a little higher than values being produced direct from the mantle in regions devoid of continental crust—a maximum present-day ratio of 0.704 in the case of Pacific oceanic basalts[22]. However, they are very much lower than contemporary values in crustal anatectic source regions containing ancient sialic basement or its erosional products. Values between 0.71 and 0.78, appropriate for such regions[8,16,23] depending on age and Rb/Sr ratio, seem to preclude an origin by direct crustal melting as described above.

Before accepting this as a rigorous conclusion, experience with strontium isotopes suggests we should beware of several ways in which the crustal melting hypothesis might be rescued. For example, guided by oxygen isotope work in the British Tertiary igneous province[24], it has become fashionable to reassess isotope patterns in terms of hydrothermal strontium transfer between intrusive and intruded rocks. It might be suggested that measured granite samples, usually taken from the exposed upper regions of batholiths, have acquired artificially low ratios due to equilibration with their mantle-derived andesite cover. However, in view of so many similar values having been determined from many different regions and erosion levels, I doubt that such an equilibration process is particularly important except in a local sense. The validity of strontium isotope interpretations can be checked by looking for ^{18}O depletions inherited from hydrothermal alteration[25], and the case for making parallel isotope measurements of strontium and oxygen in future work of this type is becoming recognised.

Perhaps a more significant method of producing low initial ^{87}Sr/^{86}Sr ratios by crustal fusion would be if the deep source region had a low Rb/Sr ratio. There is little disagreement about strontium concentrations in the continental crust and an average value of about 375 p.p.m. seems appropriate[26]. Crustal rubidium concentrations are more widely debated[26,27], but values close to the average adesite[28] (about 40 p.p.m.) seem appropriate and yield an average Rb/Sr ratio near 0.1. Bearing in mind the strong upward crustal concentration of rubidium[29], the incrementation rate of ^{87}Sr/^{86}Sr in buried crystalline basement might be less than 0.004 in 10^9 yr (corresponding to Rb/Sr=0.1). It follows that ratios normally ascribed to mantle could be derived from a relatively old lower crustal source region of low Rb/Sr. Of course, this incrementation rate is rather low in comparison to the mature ^{87}Sr/^{86}Sr ratios quoted earlier for exposed basement rocks, supposedly equivalent to those buried beneath younger orogenic belts, whose anatectic products would be distinguished easily.

At present this dilemma is not fully resolved but the temptation is to suggest that, since the Rb-poor basement rocks are usually in refractory granulite facies, the production of large volumes of low ^{87}Sr/^{86}Sr ratio granites from them seems most unlikely. This begs the question of how such rocks in the basement became deficient in rubidium and here it seems difficult to escape extraction by a melt phase leaving strontium partitioned in high temperature mineral residua[30] though this melt need not be indiginous and could be derived largely from the mantle. Shallow zones of unaffected old crystalline rocks, such as exposed in coastal Peru[8], would continue to accumulate radiogenic strontium by retaining their rubidium.

A final possibility is that underplating of the lower continental crust by low temperature, hydrous low ^{87}Sr/^{86}Sr mantle magmas, rapidly encountering their solidus temperatures, yields an immature zone later available for further partial melting (see refs 12, 14, 31). This merely splits granite magma generation into a two-stage process virtually indistinguishable from a direct mantle source on the grounds of strontium isotopes.

On balance, the conclusion to be drawn from strontium isotope observations is that Cordilleran granites contain a prominent component of recent mantle derivation. The style of granitic activity in relation to tectonic processes has doubtless changed considerably over the Earth's history[32,33], but voluminous granitic rocks generally record the isotopic imprint of recent mantle derivation from the early Precambrian[34], though fossilised early Phanerozoic Cordillera (for example Caledonian younger[35,36] but not necessarily older[37] granites), right up to recent times[16–21]. Lead isotopes provide further corroboration in that such data as are available indicate derivation of young granite and older granite gneiss leads direct from primary mantle growth curves[38,39].

Crustal thickness, deformation and accretion rates

Now let us examine a second line of attack on crustal melting hypotheses. From seismic and gravity data (refs 40 and 41, for example) it is well established that continental crustal thicknesses at destructive margins are much greater than average. In the central Andes, for instance, the crust reaches a maximum of 70 km thickness beneath the volcanic Cordillera[41], whereas 35 km is more typical of inactive regions. How does the crust locally acquire this great thickness? There are two possibilities: (1) crustal shortening whereby material is piled up due to laterally compressive forces produced where two plates are colliding and (2) thickening due to the addition of material vertically from the underlying mantle. Unlike continent–continent convergence zones, such as the Alps and Himalayas where strong compressive folding and overthrusting are in evidence[43], the field data from active ocean–continent boundaries, the sites of Cordilleran batholiths, reveal a striking lack of compressive tectonics. The intrusion of the Peruvian granites apparently created a tensional stress regime opening fracture systems which were the sites of block faulting, vertical movements[44] and even possibly crustal extension rather than shortening. The conclusion is that where two masses of like density converge the result is diastrophic whereas, at destructive margins, ocean crust and upper mantle are not forced down but dive quietly beneath continental crust with apparent ease.

Thus we have another significant difficulty for the crustal melting origin of granites. These rocks occupy about 25% of the crustal volume along destructive continental margins (average estimate based on various interpretations: refs 8, 41, 44–46) and, if we exclude thickening by crustal shortening, a large proportion of this material must be new crust recently derived by mantle melting. The other more positive candidates for derivation from the mantle are the extrusives, mainly andesites, but their volumes are too small to account for crustal thickening alone as they are essentially a veneer reaching only several km in thickness at maximum[47]. These concepts are best illustrated by a simple numerical estimate of the modern rate of crustal evolution involving both contemporary intrusives and extrusives. As a type example we can use the young Peru Coastal Batholith region, for which we now have abundant data[5,8,9,19,20,21,40,41,44,47]. The volume of crust produced by igneous events in this region during the last 10^8 years can be estimated at 1.2×10^6 km^3, based on a width of 60 km normal to the margin, a length of 1,000 km in Peru, and a material thickness of 20 km. The rate of crustal evolution from igneous activity in Peru is therefore about 0.012 km^3 yr^{-1} where "evolution" includes any recycled products of crustal fusion in addition to new material.

Now, in terms of crustal growth Peru was chosen because it probably represents an average accretion rate between the more dramatic effects of intracontinental mountain building, despite crustal shortening, and the lesser volumes involved in island arcs. To advance the argument we can estimate the contemporary crustal evolution rate at $0.012 \times 40{,}000/1{,}000 = 0.5$ km^3 yr^{-1} as I am persuaded (R. Oxburgh, personal communication) that we should consider about 40,000 km length for the world's recently active subduction zones and recently developed intracontinental margins. Again, this rate would include any recycled crustal fusion products. Obviously there will have been some erosion over the time spanned, allowance for which would slightly increase the rate estimated above. However, the amount will be too small to be significant in this approximate calculation, especially as much of the eroded material is reconstituted as continental crust by uplift at intracontinental collisions or by accumulation on the continental shelf. (For example, the Atlantic bordering shelf regions receive a surprisingly large proportion of the Andean erosion products because of eastward drainage[48]—relatively little sediment accumulates in the Peru–Chile trench[40].)

Accepting that crustal evolution is occurring at about 0.5 km^3 yr^{-1}, it follows that if all this is new material added to the crust, in which case our evolution rate becomes the crustal growth rate, 10,000 Myr would be required to produce all 5×10^9 km^3 of continental crust which now exist. Of course, it seems highly likely that accretion rates would have been rather higher in the past—a time-average of 1.1 km^3 yr^{-1} is required over the Earth's history[12]—and our modern figure of about half the time average is consistent with the decay of long-lived radioisotopes having reduced modern heat productivity to about a quarter of its initial value[49].

If we drop crustal growth rates to include only the extrusive component of destructive margins then a rate nearer 0.1 km^3 yr^{-1} would result, because intrusives predominate over extrusives. The observed crustal thickening at destructive margins could then not be achieved without severe shortening, and it is also difficult to see how continents could even have reached their present volumes without disproportionately rapid early accretion rates. Unfortunately, numerical estimates of accretion rates can never be better than highly approximate. Yet on balance, the evidence from thickening and crustal growth again demands that Cordilleran granite magmas be derived from mantle depths, whether this is by a direct melting and emplacement event or by the indirect two-stage process mentioned earlier.

Andesites, granites and mantle melting

If granite batholiths owe their origin to mantle melting, we should return to the experimental data to consider whether the observed time–space–composition relations can be produced in this revised context. In order to produce magmas over the entire lifespan of a destructive margin it is necessary to continuously replenish the source region or igneous activity would have limited life. Some involvement of subduction zone materials is implied either as a source of melt or of volatiles capable of melting overlying mantle[50].

A good starting point is to consider andesite genesis and to extend the argument later for granites. High pressure experimental studies[51], ranging up to 40 kbar, indicate that primary andesite magmas can be produced by partial fusion of subducted, amphibolitised ocean crust[31,52] corresponding to quartz eclogite[15] after dehydration. However, certain other difficulties have been encountered in generating andesites by simply melting subducted ocean crust[53,54] since 25–50% partial melting would be required to account for both the SiO_2 content and Fe/Mg ratios of average andesites. This degree of melting would dilute incompatible, large ion lithophile (LIL) trace elements yielding concentrations several times lower than observed even assuming their complete partitioning into the melt phase. Consequently, it has been necessary to devise rather more sophisticated mechanisms to account for andesite geochemistry and basically there are two possibilities: (1) Magma generation occurs within the subduction zone, satisfying major element andesite requirements, followed by enrichment in LIL elements during ascent by scavenging[56] of the overlying refractory ultrabasic mantle and, possibly, lower crust (2) The hydrous subducted lithosphere dehydrates[31,57] releasing volatiles, already enriched in LIL elements, into the overlying dry ultrabasic mantle causing incipient melting there. Only 5–10% melting is required in this case to produce andesites which are more likely to satisfy both major and minor element constraints[54].

Following Ringwood[15], Thorpe *et al.*[55] have provided an interesting bridge between these two ideas by deriving a garnet pyroxenite LIL-rich wedge over the subduction zone which is later able to melt giving andesite. This is a continuous process active so long as subduction continues. In this way, the variable initial $^{87}Sr/^{86}Sr$ ratios for andesites are produced[47] as radiogenic strontium accumulates for different times in a temporarily Rb-rich source region. However, Spooner[52] has shown that some ocean crustal rocks may increase their $^{87}Sr/^{86}Sr$ ratios by hydrothermal exchange with seawater already enriched in a continent-derived strontium component. Involvement of such materials in the production of melt beneath a Cordilleran margin provides a source for initial strontium isotope variability directly, without necessitating a complex mechanism.

It seems that a mechanism for producing andesite magmas at mantle depths is evolving, but what of granite magmas? At first sight there are problems because partial fusion of upper mantle materials cannot directly produce acid liquids[13,51]. However, if one defines the term "granite" more rigorously it is immediately obvious that the average composition of most batholiths lies between quartz diorite (tonalite) and granodiorite, rather than granite in the strict sense. Indeed, if we ignore the limitations of rock nomenclature based on grain size, the similarity between the material in batholiths and volcanic andesites on geochemical grounds is quite striking. W. S. Pitcher (personal communication) and Myers[58] have commented on these geochemical similarities in Peru: increasingly it is becoming evident that many of the intrusive centres are fossilised magma conduits which fed the overlying extrusives. Apparently tonalite (that is, andesite) magmas rose by stoping and cauldron subsidence towards the surface, locally generating a varied compositional suite by the late stage secondary differentiation process described earlier. Some assimilation or partial melting of crustal material en route to the surface is probable, and is supported by the secular changes towards higher initial strontium isotope ratios during mid-Cretaceous to Quaternary Andean plutonic activity[21]. Indeed, this process may be an essential part of producing a refractory, Rb-poor basement. Crustal melting experiments are relevant here, and show that mantle-derived tonalite melts should enter the crust with enough thermal energy gradually to drain the lower crust of near minimum melting components. I would attribute the primary composition trend (see introduction) on a time scale of 10^8 years in Cordilleran batholiths to the gradual raising of crustal temperatures during the active cycle so that both mantle magmas can assimilate at higher crustal levels to become relatively granitic, and these more granitic magmas can reach higher levels before being trapped by their melting curves[12,59]. Of course, crustal assimilation is limited by the constraints discussed earlier in this paper, but an andesitic magma need only increase its volume by between 25 and 50% to resemble the most acidic, volumetrically significant adamellites of Peru. As more data become available further small changes towards systematically higher initial ^{87}Sr/^{86}Sr ratios (see ref. 21) should be traced through the primary time–composition trend of Cordilleran granites.

The consanguinity of intrusive and extrusive magmas at destructive plate margins seems to remove the experimental objections to furnishing batholiths at the expense of mantle. The arguments given in this paper suggest that those who advocate exclusive derivation of Cordilleran granites by reprocessing of existing continental crust should seriously contemplate a revision of their thoughts. The onus is on them to show how Andean-type crustal thickening and low initial ^{87}Sr/^{86}Sr ratios in Cordilleran granites are produced without mantle involvement.

I thank the participants in a recent Herdman Geological Society symposium at Liverpool University for their discussion following a lecture on this subject.

Rates, sample sizes, and the neutrality hypothesis for electrophoresis in evolutionary studies

Vincent M. Sarich

Departments of Anthropology and Biochemistry University of California, Berkeley, California 94720

It is shown that electrophoretic genetic distance estimates are highly correlated with albumin immunological distances between the same pairs of species. The bimodality of rates of electrophoretic differentiation at various loci is then documented and the electrophoretic clocks involved are calibrated. The differences between the systematics and population genetics uses of electrophoretic data are then discussed. Finally, a direct electrophoretic test of the neutral alleles hypothesis is presented and exemplified on a set of Thomomys bottae-umbrinus *data.*

GENOMIC differentiation between diverging lineages begins as soon as their gene pools have developed a sufficient degree of reproductive isolation. Recently it has become possible to provide direct measures of the degree of such differentiation through the comparative biochemical techniques of amino acid sequencing, DNA hybridisation, electrophoresis, and immumology. As amino acid sequencing is much too time-consuming for routine application to evolutionary studies, and DNA hybridisation untested in detail, most of our current estimates of biochemical genetic distances derive from electrophoretic and immunological comparisons of proteins from species of interest. Electrophoresis, in particular, has become the favourite tool of those wishing to apply protein data to problems in systematics and population biology. Nonetheless, few, if any, studies have been carried out to develop an appropriate molecular context within which the meaning of the electrophoretic data could be properly comprehended. We especially lack direct information as to the rates of amino acid substitution in the various proteins used in electrophoretic studies, which makes it difficult to tell whether the calculation of a single genetic distance from data involving numerous loci is a legitimate exercise, and, if so, how to relate these distances to a possible time scale. Our approach to this problem began with a comparison of electrophoretic and immunological distances for the same pairs of species. The results of that study led to an appreciation of the striking bimodality in the observed rates of protein electrophoretic evolution, of the ready availability and use of the set of rapidly evolving proteins to easily deal with levels of relationship heretofore inaccessible to the molecular systematist, and, finally, to the development of a direct test of the neutral alleles hypothesis in explaining electrophoretic polymorphisms.

We can begin with a definition of the distance measures used. For electrophoretic comparisons, Nei has introduced a measure of genetic distance, D, where D is the average number of electrophoretically detectable substitutions per locus between the two populations being compared[1,2]. If x and y are the frequencies of the i allele in populations x and y, then the measure of genetic identity (I) is given by the equation

$$I_{xy} = \frac{\Sigma x_i y_i}{(\Sigma x_i{}^2 \Sigma y_i y_i{}^2)^{1/2}}$$

where the summation is over all alleles and all loci compared, and $D = -\log S$.

For the immunological comparisons, we use the microcomplement fixation immunological distance (ID)[3], where the ID between two homologous proteins is equal to five times the % sequence difference between them[4]. For the proteins whose immunology will be discussed here, albumin and transferrin, one ID unit will then be equivalent to about one amino acid substitution.

Electrophoretic genetic distance and time

The albumin immunological, and Nei electrophoretic, distances for 76 pairs of species were measured and compared (Fig. 1). There is obviously a strong correlation ($r = 0.82$) between the two measures of genetic distance, which, since different loci are being studied, suggests that each is a function of a third variable —most probably time. Ample documentation of the time-dependent nature of the vast majority of amino acid substitutions in a variety of organisms has been made in the last 15 years[10,11]—so that, for example, one can speak of an albumin 'clock', and document that it generally keeps rather good time[12]. Any such clock is necessarily a statistical one, and the comparison of two of them—in this case, the albumin and electrophoretic clocks—has to be carried with this fact well in mind. Each point in Fig. 1, considered in a time dimension, then becomes a probability ellipse. Because the number of substitutions counted in albumin immunological comparisons is appreciably greater than the number counted for the corresponding typical electrophoretic study involving 20–25 loci, the long axis of the ellipse will be parallel to the D axis. This is approximated in Fig. 1, where the dashed lines encompass an area within one electrophoretic standard error[1] of the regression line. The standard error is given by

$$\text{s.e.} = \left(\frac{1-I}{nI}\right)^{1/2}$$

where n is number of loci. To a first approximation, then, if the albumin and electrophoretic clocks were keeping perfect time, 2/3 of all the points should fall within the dashed lines. Remarkably enough, except for the cluster of seven points involving the kangaroo rat species *Dipodomys ordii*, they do. For *D. ordii*, presumably, relative to the actual phyletic distance separating it from other kangaroo rats, the albumin distance is uncharacteristically low or the electrophoretic distance too high. Immunological studies of *Dipodomys* and other geomyoid transferrins[7] give a distance between *ordii* and other *Dipodomys* species in line with the electrophoretic distance, suggesting that in this case it is the albumin immunological distance which is misleading.

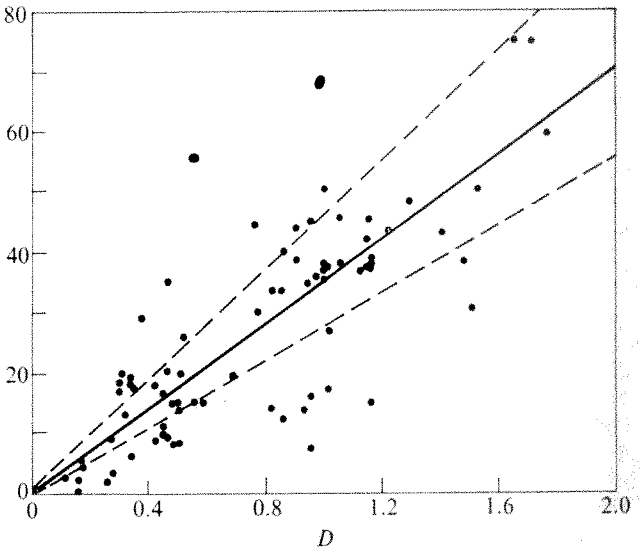

Fig. 1 Microcomplement fixation immunological distances are plotted against the electrophoretic Nei D values for the same species pairs. A preliminary version and discussion of these data have been presented previously (V.M.S., L. R. Maxson and A. C. Wilson, paper presented to the Society for the Study of Evolution, December 1973). The comparisons use published electrophoretic data on *Dipodomys*[5], *Peromyscus*[6,7], *Hyla*[8], and *Anolis*[9]. Other electrophoretic data on *Sigmodon* were provided by W. E. Johnson and R. K. Selander, on *Anolis* by G. C. Gorman, and on *Thomomys* by S. Y. Yang and J. L. Patton. All of the albumin immunological comparisons were carried out in this laboratory. The dashed lines indicate the standard errors of the electrophoretic D values. $r = 0.82$ (76 points).

It is thus evident that there is an electrophoretic clock and that it can be calibrated in terms of the albumin clock—not so much, it must be emphasised, because of earlier demonstrations of the strongly time-dependent nature of albumin evolution in other taxa, but because the rate of albumin evolution is known from those studies. Albumins accumulate some 100 units of immunological distance for every 60 Myr of separation[12], and, from Fig. 1, AID $= 35D$. Thus it takes, on the average, 20 Myr for a typical locus to accept an electrophoretically detectable substitution in one or the other of a pair of diverging lineages. Assuming a mean size of 400 amino acids[13], and that 20% of all substitutions are electrophoretically detectable, this means that the average protein sampled in the usual electrophoretic studies has a unit evolutionary period[10] in the area of 15–20 Myr. This very large figure is characteristic of the classic slowly evolving proteins such as cytochrome c and glyceraldehyde 3-phosphate dehydrogenase, and this makes one wonder as to the representativeness of these loci—especially when it comes to calculating times of divergence from electrophoretic data. For example, Nei's original calibration[1], which has been used in numerous divergence time calculations (see Table 2), set a D of 1 at about 3 Myr of separation—a figure almost an order of magnitude too low. An important complicating factor, however, has to be dealt with before realistic time of divergence calculations can be made.

Locus-dependent rates of change

This problem was first evidenced in the findings of King and Wilson for the *Homo-Pan* electrophoretic comparison[14,15]. There the D value of 0.29 for the various 'intracellular' loci sampled stood in sharp contrast to the value of 2 for the plasma protein

Table 1 Plasma protein D values and albumin plus transferrin immunological distances between the same pairs of taxa

Taxa compared	Albumin plus transferrin distance	Plasma protein D
Cercopithecus patas–C. aethiops	3	0.4
Papio–Theropithecus	7	0.6
Pan paniscus–P. troglodytes	7	0.7
Macaca nigra–M. fascicularis	9	0.7
C. patas–C. talapoin	14	1.5
Pan–Gorilla–Homo	15	1.6
M. nigra–Papio	22	2.0
Cercocebus albigena–C. torquatus	26	2.0

loci. That this result is not a statistical fluke is documented in Table 1. We list there several plasma protein D values and the corresponding albumin plus transferrin immunological distances. As transferrin accumulates amino acid substitutions some 50–60% more rapidly than albumin[16,17], one thereby obtains immunological distances sufficiently large to be reliably compared to the plasma protein D values. For the data of Table 1, the summed immunological distance corresponding to a D value of 1 is about 10 units, of which about 4, on the average, will have been contributed by the albumins. Thus the *Homo-Pan* result, if anything, slightly underestimated reality, and the plasma proteins are accumulating amino acid substitutions some 10 time more rapidly than the enzymes sampled in the electrophoretic surveys which provide the bulk of the data of Fig. 1. Nor do we see evidence to date of any particular conservation in the rate of electrophoretic change in any particular plasma protein (for example, the plasmas of *Homo*, *Pan*, and *Gorilla* show only one band with the same mobility in all three); thus we are forced to the conclusion that a rather striking bimodality describes the distribution of electrophoretically measured rates of evolution at the various protein loci. In other words, there are two sets of proteins, and one of them is accumulating electrophoretically detectable substitutions at a rate tenfold greater than the other. This rapidly evolving set includes, in addition to the plasma proteins, various other 'secreted' proteins such as those found in saliva, egg-whites, and haemolymph, the nonspecific esterases, and certain enzymes not involved in complex metabolic pathways—such as ribonuclease, lysozyme, and carbonic anhydrase; that is, many of the class 2 and 3 loci[18-20].

Setting the electrophoretic clock

This finding, as we shall see, has certain very important corollaries, not the least of which is the proper setting of the electrophoretic clock. As noted above, numerous authors have recently attempted to date divergence events among populations using electrophoretic data. These data typically, however, involve comparisons among both slowly and rapidly evolving proteins—with the latter usually including albumin, transferrin, haemoglobin, and one or more esterases. Clearly the findings reported here require a partitioning of the electrophoretic data set into two, as the clocks involved are obviously moving at grossly different rates. In essence, then, early in the process of genetic differentiation between two diverging lineages the bulk of any measured distance will be contributed by the rapidly evolving loci. This contribution will be essentially complete by 5–6 Myr of separation (that is, all the rapidly evolving proteins will have different electrophoretic mobilities by that time), and any further accumulation of genetic distance will be seen only in the slowly evolving loci. Future studies then ought to focus on a large set of rapidly evolving loci for temporally close relationships, and on a comparably sized set of slowly evolving loci once one gets beyond 4–5 M yr of separation. Specific divergence times can then be calculated once the equation AID $= 35D$ is corrected for the fact that the data from which it was derived stem from studies averaging about 3/4 slowly evolving loci and 1/4 rapidly evolving. At a D of 1, $I = 0.37$, and effectively all this similarity will have been contributed by the slowly evolving loci—thus their actual I value will be 0.37/0.75, or 0.5; corresponding to a D of 0.7. That is, in 35 M yr the set of slowly evolving loci will give a D value of 0.7, so that the corrected equations will approximate: (1) slowly evolving loci: AID $= 50D$; $T(\mathrm{Myr}) = 30D$ (2) rapidly evolving loci: AID $= 4D$; $T(\mathrm{Myr}) = 2.4D$.

We include, for heuristic purposes, a plot relating time of separation to D for a typical study where 3/4 of the loci are slowly evolving, and 1/4 rapidly evolving, as Fig. 2. In addition, we present in Table 2 some adjusted times of divergence involving data already in the literature and using the calibrations derived in this article. It might be noted that some of those adjustments produce substantial change which will have to be taken into account when reassessments of the evolutionary pictures implied are made.

Systematics against population genetics—sample sizes

At this point, before getting into more theoretical matters, it is appropriate to consider the distinction between population genetics and systematics uses of electrophoretic data. The basic interests of the population geneticist of course lie in the realm of population dynamics, and the knowledge of allele frequencies is an essential prerequisite to further work. The population geneticist, then, studies populations. The systematist, on the other hand, has as a first goal the knowledge of the evolutionary relationships among the organisms with which he is working. Thus, in assessing, for example, the evolutionary genetic distance between humans and chimpanzees, one human and one chimpanzee can give an entirely representative picture. The question therefore arises as to how many individuals per population will be necessary for a particular study, and clearly the answer to this question depends on the genetic distances involved, as well as on the rates of evolution of the loci being sampled. It then becomes vital to achieve some reliable assessment of the nature of the evolutionary relationships involved in the study at hand before, for example, undertaking the onerous and time-consuming task of surveying numerous populations with many individuals per population at 20 or more loci—as has all too typically been the case in much recent electrophoretic work. Such an assessment has to take place in stages, and it might be instructive to illustrate those stages with specific examples.

The first stage question would simply ask whether effective genetic isolation has been achieved between the populations in question. As the genetic differentiation which accompanies the development of such isolation will most readily be seen here with the set of rapidly evolving loci, one should first compare the various easily available secreted proteins—for vertebrates, this would mean the plasma proteins and the nonspecific esterases.

Table 2 Some published times of divergence calculated from electrophoretic data and adjusted according to the calibrations introduced in this article

Taxa involved and specific divergence event	Proportion fast loci	I	Published divergence time (M yr)	Calculated divergence time (M yr)	
Icteridae (blackbirds)					
Agelaiine–Quiscaline groups	0.53	0.7	0.27	1.4	ref. 21
Thomomys talpoides (gophers)					
48-chromosome New Mexico populations and others	0.36	0.845	0.23	1.2	ref. 22
Peromyscus (deer mice)					
boylei and *truei* species groups (excepting *polius*)	0.47	0.68	0.24	2.1	ref. 23
Drosophila					
virilis–littoralis–montana species groups	ca0.7	0.37	0.75	3.9	ref. 1

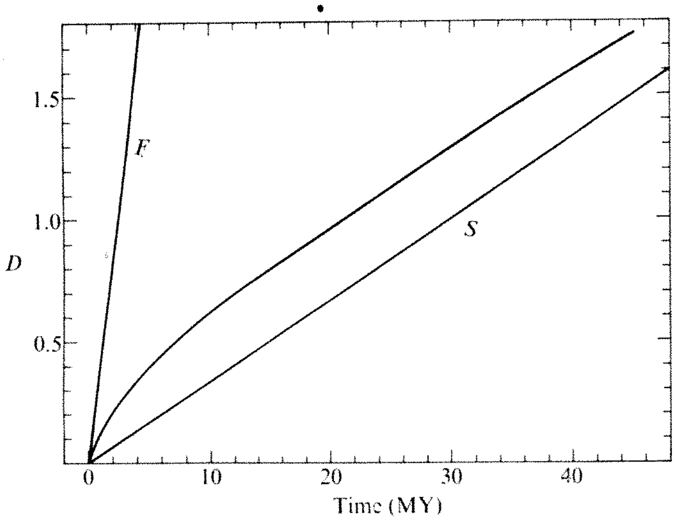

Fig. 2 The accumulation of electrophoretic genetic distance (*D*) as a function of time for the rapidly evolving proteins (F), slowly evolving proteins (S), and a mixed system involving 3/4 slowly evolving, and 1/4 rapidly evolving proteins (unlabelled line) calculated according to the calibrations discussed in the text.

With reasonably fresh material one ought to be able to readily see some 25–30 bands on a single gel. These could be compared most simply in two individuals as the number with the same mobility divided by the number counted in both. Thus the only way that two individuals drawn from the same gene pool could give a *I* value of less than 1 would be for them to be homozygous for different alleles at one or more loci. The maximum probability for such an occurrence is 1/8 (at a polymorphic locus with two alleles at a frequency of 0.5)—thus even if 1/3 of our 25–30 loci were polymorphic, it would be unlikely for the two individuals to be counted as different at more than one locus. Even this rather low 'noise' level can be effectively eliminated by comparing two individuals per population—the 1/8 probability per locus then drops to 1/128. Beyond this one gains nothing until a large enough number of alleles is counted so that one can reliably speak of allele frequencies, and the required 30 or so individuals now increases the workload by more than an order of magnitude without anything approaching a commensurate gain in effective resolving power. In fact, if one takes into account observed heterozygosity values and the evolutionary rates calculated here, it becomes evident that very little indeed in the way of resolving power is contributed to the systematics of a group by that component of genetic distance due to allele frequency differences at the slowly evolving loci. Resolving power over the last few million years of relationship is far more efficiently gained through the use of the rapidly evolving set of loci—most simply by the band counting approach just outlined, and ultimately by allele frequency comparisons at those loci which are polymorphic. Appropriate attention to these considerations, with emphasis on increasing the number of slowly evolving loci in the study, should then greatly facilitate routinely working with evolutionary relationships extending over the last 50 MY or so ($D_{\rm slow} = 1.6$). If, for example, one could routinely work with 40 slowly evolving loci, this would mean that the effective rate of electrophoretic substitution along any given lineage is one per 1.5 Myr; that is, the average ultimate resolving power is 1.5 Myr up to about 50 Myr of separation. It is, of course, 10–50-fold better in the range 0–6 Myr due to the ready availability of a large set of rapidly evolving loci.

A practical test of this 'band-counting' approach to the electrophoretic systematics of closely related forms is available among the kangaroo rats (*Dipodomys*). Patton, MacArthur, and Yang have recently reported[24] that *Dipodomys heermanni* is clearly composed of two quite distinct species, with one more closely related to a third, *D. panamintinus*, than it is to the other *heermanni* (now renamed *californicus*). That study surveyed 22 loci and some 100 individual kangaroo rats. Yet one gel with one individual per population at issue—using band-counting for the plasma proteins and liver esterases—can give congruent results; although, of course, the *D* values obtained are appreciably higher (Table 3). It should also be noted that for many taxa of interest populations are not realistically available, and this approach enables one to learn a great deal about relationships at taxonomic levels heretofore mysterious using sample sizes of only one or two individuals per population. Such a preliminary effort among the Old World monkeys, complementing an already completed immunological study, has already been reported[25]. We have also been able to obtain the first reliable measures of genetic distance separating the pygmy chimpanzee (*Pan paniscus*) from the more common *Pan troglodytes*, and the Eastern and Western lowland gorillas. In each case the plasma protein *D* value was 0.7, suggesting separations on the order of 2 Myr ago. The corresponding *Pan-Homo-Gorilla* distances are 1.6–1.7, consistent with the summed albumin and transferrin immunological distances among the three of 15 units (Table 1).

These results also suggest that some degree of caution should be exercised in the use of genetic distance criteria to assess the taxonomic levels at which populations ought to be separated. Obviously the genetic distances obtained will be very dependent on the loci included in the study, and a 'species level' *I* value of 0.85 for a study involving a preponderance of slowly evolving loci might well become a 'genus level' value of 0.3 when looking at the rapidly evolving set. Thus the *D. heermanni–D. panamintinus* *I* value of 0.9 (ref. 24), which might be used to argue for conspecificity, becomes 0.6 when the plasma proteins and liver esterases are used. One can, however, foresee a possible negative effect of this newly increased resolving power when dealing with lineages of relatively recent origin. This will stem from the marked proliferation of recognisably different (at the genetic level, at least) populations which are not exchanging genes (that is, which have fixed different alleles), and which, therefore, can be seen as representing different 'species'. For mammals, this proliferation will certainly occur among the rodents—and one can only hope that this increased resolving power might be used to raise our level of understanding of the dynamics of the evolutionary process, and not to make it so much easier to play the 'splitting' game in formal taxonomy.

A direct test of the neutral alleles hypothesis

Finally, we can consider the test of the neutral allele hypothesis. We know that, for a neutral allele polymorphism, the length of time a given lineage remains polymorphic will depend only on the size of the populations along it. The probability of a given locus being polymorphic, on the other hand, is a function of the rate of amino acid substitution at that locus. Thus rapidly substituting loci will be polymorphic more often, thereby being more likely to contribute to population heterozygosity—again, to emphasise, for neutral allele situations. For such situations, then, heterozygosity per locus will be proportional to the rate of amino acid substitution at that locus. To the extent that this is actually descriptive of a body of data, we argue that such a data set is consistent with the neutral hypothesis; to the extent that it is not, we are encouraged to look for specific selective effects. One case where the neutral hypothesis does seem entirely adequate to explain the observed data involves a study of 25 *Thomomys bottae-umbrinus* (pocket gopher) populations, where at least 30 individuals per population were surveyed at 23 loci

Table 3 A comparison of the results obtained with the plasma proteins and liver esterases using one individual per population with those obtained in the usual population genetics approach in *Dipodomys*

	D.h.(5)	D.p.	D.h.(4)
Dipodomys heermanni (5-toed)	0	0.47	1.60
Dipodomys panamintinus	0.08	0	1.35
Dipodomys heermanni (4-toed)	0.24	0.15	0

The numbers above the diagonal are the plasma protein plus liver esterase *D* values using one individual per taxon. Those below the diagonal were obtained using 18 'slow' and 4 'fast' loci with a total of 100 individuals[24].

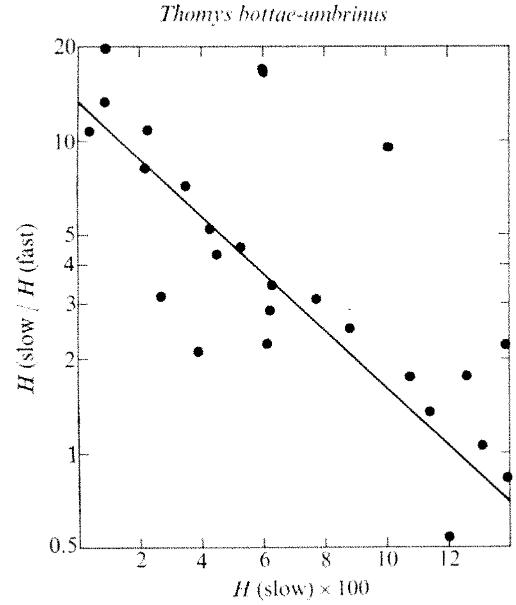

Fig. 3 The ratio of heterozygosity (H) values in a series of *Thomomys bottae* and *umbrinus* populations for sets of 18 slowly evolving, and 5 rapidly evolving loci are plotted against the H values for the slowly evolving set. The justification for the log-linear plot is presented in the text.

(18 'slow', 5 'fast')[25]. The H values for the 'fast' and 'slow' sets of loci were then calculated, and plotted as log H (fast)/H(slow) against H(slow) for each population (Fig. 3). The log transform is to allow for the fact that the number of potentially detectable electrophoretic alleles in a population is limited by the integral nature of charge changes—thus the H(fast)/H(slow) ratio could not increase as a linear function of H(slow). It should be noted that H(fast) clearly does increase as H(slow) increases and, extrapolating to $H(\text{slow}) = 0$ gives us a H(fast)/H(slow) intercept of 13, which is, considering the statistical uncertainties involved, remarkably similar to the D(fast)/D(slow) value of about 12 derived previously. It is difficult to see how this quantitative congruence between rates of substitution and heterozygosity levels at particular sets of loci could be the result of anything other than the random walking of neutral alleles.

Summary and suggestions for further work

These findings should be considered indicative of an area in which a great deal of further work needs to be done, and not necessarily representative of a general pattern. The data of Fig. 1 certainly argue forcibly for the strongly time-dependent nature of rates of electrophoretic differentiation, but there is, nonetheless, adequate space left for a certain degree of selective maintenance of various polymorphisms. Appropriate further testing of the neutral allele hypothesis in the manner just described awaits a sufficiently large sampling of rapidly evolving loci so that the sample sizes of the two sets of loci are comparable. This should be a relatively simple matter in most vertebrate groups, where one should certainly be able to routinely score 15 plasma protein, and 5–10 esterase, loci. For the very large and important *Drosophila* data set, however, with which so much of the neutralist-selectionist controversy has been concerned, it will be necessary to document a reasonable sample of rapidly evolving loci prior to carrying out these tests. Presumably these would be most readily available in the haemolymph and among the larval proteins and non-specific esterases, though clearly the rates of differentiation at the various enzymatic loci ought also to be compared to see if any of those are especially rapidly evolving. The available data, then, are explicable within a simple framework involving a very small number of variables, and the next step consists of expanding the taxonomic base within which this simple framework can be seen as operative.

I thank W. E. Johnson, R. K. Selander, and especially G. C. Gorman, S. Y. Yang, and J. L. Patton for unpublished electrophoretic data and sera for carrying out the immunological comparisons; D. Shochat and H. Dessauer for antisera to *Anolis extremus* albumin; and A. C. Wilson for helping to initiate this study. I also thank J. Wyles and A. Hill for technical assistance, and L. R. Maxson, J. L. Patton, P. Hedrick, G. Sensabaugh, S. Beverley, and J. E. Cronin for helpful discussion; the National Science Foundation for financial support to me and to A. C. Wilson; and A. C. Wilson and the Biochemistry Department, UC Berkeley for making the laboratory facilities available.

T4 Bacteriophage-coded RNA polymerase subunit blocks host transcription and unfolds the host chromosome

Karl Sirotkin, Jane Wei & Larry Snyder

Department of Microbiology and Public Health, Michigan State University, East Lansing, Michigan 48824

T4 bacteriophage mutants selected for their ability to grow with cytosine in their DNA are defective in host transcriptional shutoff and host chromosome unfolding. The host RNA polymerase purified from cells infected by such a mutant lacks a small T4-coded subunit.

T4 BACTERIOPHAGE shuts off host transcription efficiently and rapidly but the molecular mechanism behind this remains a mystery. One reason for the mystery may be that no T4 mutants defective in host shutoff have yet been isolated. Since T4 probably uses the host RNA polymerase for all its transcription[1,2], inactivation of the polymerase cannot be involved in shutoff. During infection however, various T4 coded polypeptides bind to the host RNA polymerase. These include the products of T4 genes *55* (refs 3 and 4) and *33* (refs 3 and 5) and of two other unidentified genes. The latter two polypeptides, molecular weights 15,000 and 10,000, were assigned the numbers 2 and 4, respectively, by Stevens[3]. There are other polypeptides which bind loosely to the RNA polymerase[6]. In addition, the α subunit of the RNA polymerase is adenylated[7] by two distinct T4-coded activities, *alt* and *mod* (ref. 25), one of which, *alt*, is carried in the virus particle[8,9]. The adenylated RNA polymerase transcribes *E. coli* genes poorly *in vitro*[29]. Neither *alt* nor *mod* mutants affect the shutoff of host protein or r RNA synthesis *in vivo*[8], however, and none of the T4-coded RNA polymerase subunits has been implicated in host shutoff.

Besides changing the host RNA polymerase, T4 infection alters the host "chromosome". The host DNA changes its intracellular location[31] (nuclear disruption), a process requiring the T4 *ndd* gene product[10]. The highly compact structure of the host nucleoid is unfolded[12], requiring the product of the T4 *unf* gene[11]. The host DNA is degraded to mononucleotides chiefly by the products of genes *denA endoII* (refs 13 and 14) and *46*, *47* (ref. 15). All of these phenomena can proceed independently of each other[10,11]. None of them has been related in a simple way to the shutoff of the synthesis of at least the major host proteins[11].

T4 has hydroxymethylcytosine in its DNA instead of the usual cytosine[16]. It is tempting to speculate that the shutoff of host transcription and/or replication occurs when T4 causes the cell to reject DNA with cytosine for some aspect of transcription and/or replication. If this is true, T4 with cytosine in its DNA might "shut itself off". T4 mutations which permit the multiplication of cytosine-containing T4 would occur in genes normally involved in host shutoff. To test this hypothesis, and to find T4 regulatory genes, we have begun the search for T4 mutants which can produce T4 with cytosine in their DNA.

The first such mutants we have found are deficient in the function of a gene which we call *alc* (ref. 17). When cytosine-containing T4 DNA is made after infection, the *alc* gene product almost completely prevents true-late transcription. True-late mRNAs are those which require T4 DNA replication[18] to have occurred and the products of genes *33*, *55* (ref. 18) and *45* (ref. 19) to be present. Here we present evidence that the product of the *alc* gene becomes an RNA polymerase subunit, probably the polypeptide no. 2 of Stevens[3]. It is also required to unfold the host nucleoid after infection and is likely to be the *unf* gene product of Snustad and his collaborators[11]. We discuss the implications of this for the structure of the host nucleoid, and the relationship of the structure to transcriptional regulation.

Missing T4-coded polypeptide in *alc* RNA polymerase

In the original report on *alc*$^-$ mutants, we proposed that the *alc* gene product, itself non-essential, interacts with an essential part of the transcription apparatus. We proposed that this may be one of the activities which adenylate the α subunit of the RNA polymerase or may be one of the T4-coded RNA polymerase subunits. Since mutants are available which lack one or the other adenylating activity[8], we tested these first. Neither *alt*$^-$ nor *mod*$^-$ mutants were able to confer the *alc*$^-$ phenotype after recombination with T4 which makes cytosine-containing DNA. Thus, we tentatively concluded that *alc*$^-$ mutants are not simply *alt*$^-$ or *mod*$^-$. We then purified the RNA polymerase from cells after infection by an *alc*$^-$ mutant to test for the presence of the T4-coded polypeptides. Figures 1*a* and *b* show polyacrylamide gels of RNA polymerase from *alc*$^+$ and *alc1* (*alc*$^-$) infected cells respectively. The *alc*$^-$ mutant is conspicuously lacking the major peak of radioactivity in about fraction 33, but has all the others. By molecular weight determinations with known markers and by comparison with the published results of Stevens[3], we think that the missing peak is the 15,000 molecular weight polypeptide no. 2. *Alc1* was a spontaneous mutant of the *alc*$^+$ parent shown in Fig. 1*a*. Thus, we are quite sure that the *alc*$^-$ mutation caused the absence of the polypeptide in the RNA polymerase. In addition, we have done this experiment using 'mixed labels'. The *alc1* mutant infected cells were labelled with ^{35}S-methionine and the *alc*$^+$ parent with ^{3}H leucine. The infected cells were then mixed and the RNA polymerase purified as before. The polypeptide in question was only labelled with ^{3}H offering additional evidence that, after infection by the *alc1* mutant, the polypeptide is not bound to the RNA polymerase. This is not true for all apparent *alc*$^-$ mutants, however. We shall return to this point later. The *alc1* mutation does not seem to affect the synthesis of any other T4 early gene products. Thus, *alc* is probably the structural gene for this RNA polymerase-bound polypeptide.

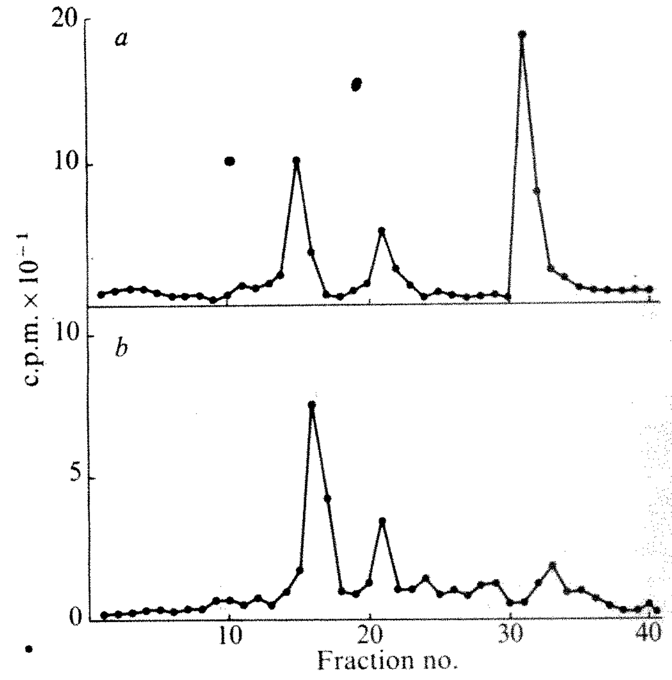

Fig. 1 An *alc*$^-$ mutant is lacking a T4-coded polypeptide on the RNA polymerase. *E. coli* B$^{\text{E}}$ (100 ml) growing in M9 without amino-acids at 30 °C were labelled with ^{3}H-leucine 5–15 min after infection. They were then mixed with 1 g of uninfected cells, sonicated, and the RNA polymerase purified by the method of Burgess[21] through phosphocellulose chromatography. The results of slicing and counting 12% SDS gels (procedure of Fairbanks *et al.*[22]) is shown. The dye front was on the right. *a*, T4-coded polypeptides on the RNA polymerase from the parent of the spontaneous *alc*$^-$ (alc1) mutant (*b*). The *alc*$^-$ mutant is clearly missing the first peak from the right in about fraction 34. We think this peak is due to Stevens' polypeptide no. 2.

Map position of *alc*$^-$ mutations

The *alc* gene product seems to be relatively non-essential in most laboratory conditions. We have found, however, that the multiplication of some *alc*$^-$ mutants, including *alc1*, is temperature sensitive. This effect is amplified in certain RNA polymerase mutants of *E. coli* of the Rif$^{\text{R}}$-2 type[24] and *alc1* will not form plaques at 42 °C on these strains. We think the temperature sensitivity is due to the *alc*$^-$ mutation because (1) a fairly high percentage (~10%) of spontaneous *alc*$^-$ mutants are temperature sensitive, and (2) we have not been able to separate the temperature sensitive and *alc*$^-$ phenotypes by recombination.

Even though we do not know the molecular basis of the temperature sensitivity we have used it to map *alc*$^-$ mutations. First, we isolated the *alc1* mutation by crossing out the amber mutation and the rII deletion which were used in its selection[17]. We then crossed this temperature-sensitive mutant with amber mutants in genes around the T4 map and selected for non-temperature sensitive, *am*$^+$ recombinants. We obtained the lowest recombination frequencies with mutants in the region of gene *31*. To localise the mutation more precisely, we constructed double mutants of the temperature-sensitive mutant and amber mutants in genes in this region. We then crossed these against

Table 1 Map position of *alc*⁻ mutations

Cross Crossover occurring	*am*H21, *alcl* × *am*H39 54 alc	*am*H39, *alcl* × *am*H54 30 alc	*am*N54, *alcl* × *am*M69 31 alc	*am*M69, *alcl* × *am*N54 alc 63
	30	31	63	31
Expected frequency *alc*⁻	~1	~1	~½	~½
Observed frequency	$\frac{50}{56}$	$\frac{57}{65}$	$\frac{43}{112}$	$\frac{56}{97}$

Map order: 54 30 31 *alc* 63

Double mutants *am*, *alc*⁻ were constructed by crossing and screening *am* progeny for temperature sensitivity by spotting on K803 Rif^r–2[23] at 42 °C. These double mutants were then crossed with single amber mutants in the region of gene 31. The *am*⁺ recombinants were spotted on K803 Rif^r–2 to determine their temperature sensitivity. Shown is the fraction of the total *am*⁺ progeny from one plate which are *alc*⁻. The amber mutants used were *am* H21 (gene *54*), *am* N54 (gene *31*) and *am* M69 (gene *63*). The *alc*⁻ mutant is *alc1*, the same mutant used in the RNA polymerase experiment in Fig. 1. *alcl* is also *unf*⁻. We have also analysed other crosses, the results of most of which were also consistent with this map order.

single amber mutants and tested the *am*⁺ progeny for their temperature sensitivity (Table 1). We have shown the map order which is consistent with the data and the crossover occurring in each case. The data support the map order gene *63*-*alc*-gene *31*.

There are four other types of mutations which have been reported to map between genes *63* and *31*. These are *r*III, *cd*, *pset* and *unf* (ref. 11). Of these, *unf* may be related to *alc* since they both might be expected to play a part in host shutoff, *unf* because it is required for the unfolding of the bacterial nucleoid and *alc* because it prevents a type of transcription on cytosine-containing T4 DNA. Thus, we studied the ability of *alc*⁻ mutants to unfold the host nucleoid after infection.

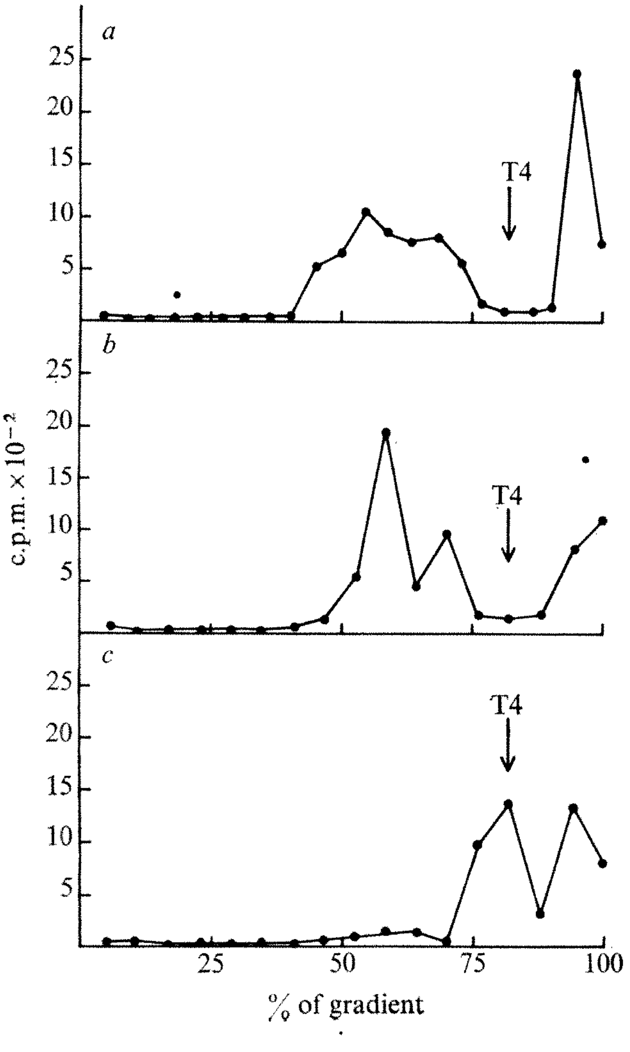

Fig. 2 Sucrose gradients of nucleoids after infection by an *alc*⁻ mutant. *E. coli* B^E (5 ml) growing at 30 °C in M9S were labelled for 1 h before infection with 16 μCi ml^{-1} thymidine (5.5 mCi mg^{-1}). They were infected at a concentration of 4×10^8 ml^{-1} at a multiplicity of infection of 5 in 10 μg ml^{-1} tryptophan. At 5 min after infection, 1.0 ml was poured into a chilled tube containing 0.1 ml of 1 mg ml^{-1} chloramphenicol. The lysis procedure of Snustad *et al.*[11] was used except that the solutions were made up as follows. Solution I: 0.1 m Tris, 6.5 mg sodium azide, 1.0 g sucrose, 0.58 g NaCl, and 9 ml H_2O. Solution II: 1.2 ml Tris, 2.0 ml EDTA, 4 mg lysozyme, and 6.8 ml H_2O. Solution III: 0.1 ml Sarkosyl, 1.16 g NaCl, 0.5 ml EDTA, and 9.0 ml H_2O. Tris was 1 M adjusted to *p*H 8.15 with HCl. EDTA was 0.25 M adjusted to *p*H 7.0 with NaOH. After 5 min for lysis, two additional steps were performed before layering on gradients. 0.1 ml of 20.0 mg ml^{-1} lysozyme dissolved in solution II were added for 10 min and then the lysate was diluted with 2.0 more ml of solution III. Five minutes later the lysate was chilled and 0.15 ml were layered on 4.7 ml 10–30% w/v sucrose gradients made up with 0.5 ml Tris, 0.25 ml EDTA, 0.25 ml Sarkosyl, 5.8 g NaCl, and 10 μl mercaptoethanol per 50 ml. There was a 0.5-ml step at the bottom made from a solution containing 0.1 ml Tris, 6.0 g sucrose, 1.0 g NaCl, 3.0 ml saturated CsCl and 3.0 ml H_2O. They were centrifuged at 4 °C for 25 min at 17,000 r.p.m. in a Spinco SW50L rotor. Fractions were collected from the bottom which is at the left. *a*, Uninfected; *b*, *am*E51, DD2, *alc2* (ref. 17), an *alc*⁻ mutant induced by hydroxylamine and back crossed three times against its parent at a ratio of 1 : 10; and *c*, the *alc*⁺ parent of *alc2*. The arrows show the peak of sedimentation of a T4 phage marker.

alc⁻ Mutants defective in host nucleoid unfolding

In 1971, Stonington and Pettijohn reported a lysis procedure which leaves *E. coli* DNA highly folded, perhaps in a similar state to its intracellular structure[20]. These compact structures, nucleoids, have a high sedimentation rate and contribute little to to the viscosity of lysates. If they are unfolded, however, after T4 infection[12] for example, their S value drops markedly and the lysates are extremely viscous.

To see whether *alc*⁻ mutations affect the T4-induced unfolding of the host nucleoid, we made sucrose gradients of nucleoids from uninfected, *alc*⁻ infected and *alc*⁺ infected cells (Fig. 2). In agreement with others, our nucleoids from uninfected cells sedimented heterogenously with an S value of about 2,000. This S value was largely unchanged by infection with the *alc*⁻ mutant while it dropped to about 1,000S after infection by *alc*⁺ T4. Thus, the *alc*⁻ mutant is defective in host nucleoid unfolding.

We also determined the time course of unfolding by *alc*⁻ mutants by measuring the viscosity of lysates of cells taken at different times after infection. The results for two independent *alc*⁻ mutants and their parent are shown in Fig. 3. Both *alc*⁻ mutants were defective in host nucleoid unfolding compared with the parent. One of them, *alc2*, probably never unfolds the host nucleoid whereas the other, *alc4*, is merely delayed about 1–2 min in unfolding. Some *alc*⁻ mutations do not measurably affect the timing or extent of host nucleoid unfolding.

Are *alc* and *unf* the same gene?

Several considerations support the conclusion that *alc* and *unf* code for the same gene product. A fairly high percentage (> 10%) of *alc*⁻ mutants are also measurably *unf*⁻. Those *alc*⁻ mutants which are not measurably *unf*⁻ are also those which make reduced amounts of late gene prducts when cytosine-containing T4 DNA is made (data not shown). We have also obtained what seem to be partial revertants of the *alc1* mutation (that is, they are less *alc*⁻). These have also become *unf*⁺ to varying degrees. The temperature-sensitive mutation which we have mapped is inseparable from *alc* by recombination and maps in the same region as the *unf* mutation of Snustad *et al.*[11]. So far, those *alc*⁻ mutations which confer the most temperature sensitivity have been the most completely *unf*⁻. The *alc2* mutant used was back-crossed against its parent three times at a ratio of 1:10, selecting the *alc*⁻ phenotype each time; it was still *unf*⁻. All of these observations support the conclusion that *alc* and *unf* are the same gene. However, we have not rigorously excluded two other possibilities. One of these is that *alc* and *unf* are neighbouring genes and those *alc*⁻ mutants which are also *unf*⁻ are deletions spanning these two genes. The existence of partially *unf*⁻ mutants such as *alc4*, however, which is also intermediate in its temperature sensitivity and *alc*⁻ phenotype, argues against the deletion hypothesis. Also, the high frequency of *alc*⁻,-*unf*⁻ mutants has already been given as evidence for point mutants. The other possibility is that *alc*⁻, *unf*⁻ mutants are double point mutants, *alc* and *unf* are adjacent genes, both the *alc*⁻ and *unf*⁻ mutations enhance the multiplication of cytosine-containing T4, and the temperature sensitivity is due to the *unf*⁻ mutation. However, we think these alternative explanations are very unlikely and that *alc* and *unf* are the same gene.

If *alc* and *unf* are the same gene why are not all *alc*⁻ mutations measurably *unf* deficient? The most likely explanation is that T4 mutants which are only partially defective in *alc* function can still multiply with cytosine in their DNA to make a plaque; but are not as temperature sensitive and are scored as *unf*⁺ in our unfolding test.

Implications for host shutoff and *E. coli* nucleoid structure

Although *alc* might be expected to play a part in host shutoff, *alc*⁻ and *unf*⁻ mutants do not affect the timing of shutoff of synthesis of the host proteins one sees on polyacrylamide gels (ref. 11 and our unpublished observations). Since there could be a translational shutoff superimposed on the transcriptional one, however, we looked at the shutoff of host RNA synthesis directly by testing to see whether any RNA synthesised after infection by an *alc*⁻ mutant can hybridise to *E. coli* DNA. The results are shown in Table 2. It is clear that the *alc*⁻ mutation affects the shutoff of the synthesis of at least some *E. coli* transcripts. Thus, selecting T4 mutants which could multiply with cytosine in their DNA has led to the discovery of a host shutoff gene, *alc*.

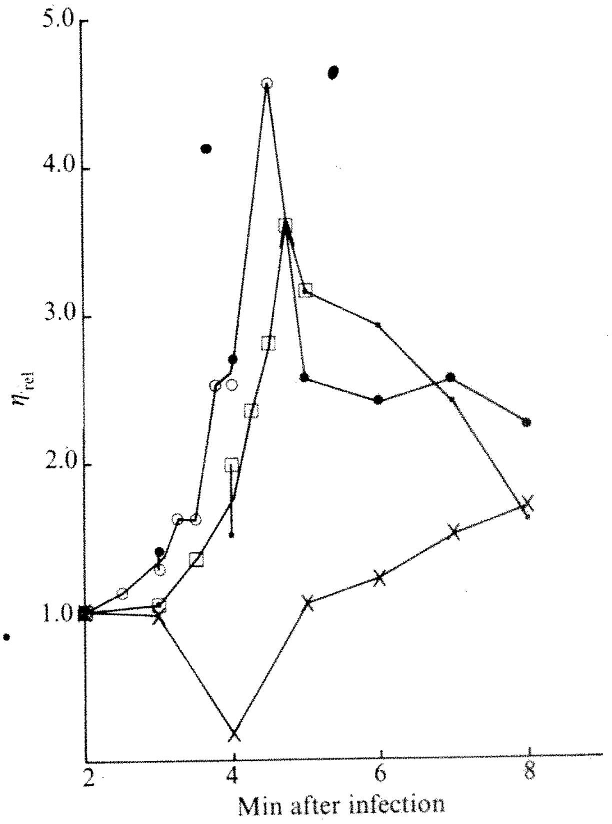

Fig. 3 Time course of unfolding of host nucleoids after infection by *alc*⁻ mutants. Cells were infected and all 5 ml lysed as in Fig. 2. 12 min after solution III was added, the viscosity of the lysate was measured without previous centrifugation by measuring the rate of movement in mg s⁻¹ through a 20-gauge needle 4 cm long. The ratio of this number to that obtained from lysates of cells at 2 min after infection is plotted. Lysates of uninfected cells flowed at close to the same rate as cells collected 2 min after infection and both were only slightly slower than H_2O. The process of measuring the viscosity of all the samples took less than 15 min and the uninfected cell lysates were still not viscous at this time. The closed and open figures of each type represent different experiments. We drew the line through the midpoint when the results were slightly different for the same time after infection. (○), *am*E51, DD2 (ref. 17); □, *am*E51, DD2, *alc4*; ×, *am*E51, DD2, *alc2*.

Table 2 Hybridisation of RNA labelled after infection by an *alc*⁻ mutant to *E. coli* DNA

RNA ^{3}H	Labelling time	c.p.m. Input	c.p.m. Hybridised	% of RNA Hybridised	% of RNA which is *E. coli*
Uninfected	2-min pulse	8,3[illegible]7	1061	12.7	(100)
T4+	4–6	4,736	107	2.26	17.8
	8–10	3,033	31	1.04	8.2
	14–16	2,557	103	4.0	31.5
alc1	4–6	5,048	224	4.4	34.6
	8–10	3,495	196	5.5	43.0
	14–16	2,840	261	9.2	72.5

RNA was pulse labelled at the times indicated in M9 medium at 30 °C with 10 μCi ml⁻¹ ^{3}H-uridine (5 Cimmol⁻¹). The phage were *alc1* which had been crossed against the wild type (T4⁺) to remove the *am*E51 and DD2 mutations[17]. The multiplicity of infection was 10 and tryptophan was added at 10 μg ml⁻¹ before infection. Surviving bacteria were less than 0.1% at 2 min after infection. The RNA was extracted three times with phenol at 60 °C by the Method I of Bolle *et al.*[18], ethanol precipitated, treated with DNase (5 μg ml⁻¹) in 0.1 M Tris-Cl *p*H 8.0, 0.01 M $MgCl_2$ for 15 min at 37 °C, extracted twice and reprecipitated with ethanol. Hybridisation was with 20 μg ml⁻¹ *E. coli* DNA[30] for 40 h at 60 °C in 2SSC. The hybrids were treated with RNase (12 μg ml⁻¹ RNase A at 37 °C for 15 min), collected on presoaked Millipore filters, and washed with 0.5 M KCl, 0.01 M Tris, *p*H 7.5. The specific activities of the RNAs were from top down, 10.6, 6.76, 4.0, 3.32, 7.8, 5.85, and 4.27 c.p.m. ng. The percentage of RNA which is *E. coli* was determined by dividing the percentage of input counts which hybridised by the percentage of the uninfected labelled RNA which hybridised. This number is affected by changes in the relative concentrations of *E. coli* RNA species so should only be considered qualitative. It is perhaps surprising that *E. coli* transcription can continue so late into infection when the host DNA is being degraded. This RNA is presumably being made on fragmented DNA.

If *alc*$^-$ mutants are defective in the shutoff of host transcription, why are they normal in the shutoff of the host proteins one sees on gels? One possibility is that there is a translational shutoff which is independent of transcriptional shutoff, and evidence has been presented for such a translational shutoff by T4 (refs 27 and 28).

Host RNA is still being made after infection even by *alc*$^+$ phage, as also observed by Kennel[27]. In fact, at late times the percentage of RNA synthesis attributable to the host apparently increases (see Table 2). Either *alc* is inefficient in its shutoff of host transcription or it is only responsible for shutting off a subset of the host RNA synthesis. Accordingly, we are undertaking experiments to determine whether all types of host transcription are shut off equally by *alc*.

In conclusion, we have presented evidence that an RNA polymerase subunit can cause the host nucleoid to unfold. Since mutants which lack the function of this subunit allow increased transcription of the host genome after infection, perhaps the *alc* gene product prevents the synthesis of RNA which holds the nucleoid together. In this connection, it has been reported that treating cells with rifampin causes the unfolding of the nucleoid[26]. Other types of experiment also suggest that RNA is important in maintaining the highly folded state of the host nucleoid since RNase treatment can cause it to unfold[20]. According to one model, then, the unfolding of the host chromosome is merely a consequence of shutting off host transcription by *alc*. However, another possibility should be considered: the unfolding of the host chromosome by *alc* may cause host transcription to cease. If so, perhaps T4 does not make RNA on cytosine-containing T4 DNA because *alc* causes it to "unfold itself". It should be possible to design experiments to test these, and other, hypotheses. Because of this, the T4 *alc* gene product promises to be an important tool in the study of the modes and mechanism of prokaryotic transcription. It also promises to be useful in the study of the roles of RNA and RNA polymerase in maintaining the structure of the prokaryotic chromosome.

Evidence from optical polarisation for a galactic-scale uniform magnetic field in M104

LINEAR polarisation of light has been observed in several galaxies[1–4], but the only previous detailed polarisation pattern has been mapped in M82[2,3,5,6] from which information about the luminous and physical structure of the galaxy has been deduced[7]. Clearly, detailed knowledge of the polarisation pattern in a nebula is a powerful tool for further understanding of the nebula. In this letter we present a map of the linear optical polarisation of the Sombrero Galaxy (M104) giving the first clear evidence for the existence of a magnetic field which maintains the same projected direction over an estimated volume of some 10^3 kpc^3.

The observations were made on the 1-m telescope of the Wise Observatory, Israel during the period May 20–24, 1976 using the B waveband of the UBV system. The technique used has already been described[8] and uses the Durham polarimeter and the Royal Greenwich Observatory 4-cm electronographic camera to record the analysed light on nuclear emulsion. The electronographic plates have been digitised on the PDS machine at the Royal Greenwich Observatory with a bin size of 1.4 × 1.4 arc s. The polarisation measurements have been determined at each point over an integration area of 7 × 7 arc s (that is, over 25 digitisation bins). Measurements have been made at 1,000 points within the galaxy. Calibration checks on the performance of the polarimeter have been made using standard polarised stars as references[8]. It has not been necessary to make instrumental corrections.

The resulting polarisation map is shown in Fig. 1. Our technique eliminates any non-uniformity of the electronographic emulsion as we make two independent measurements at each point and these agree in all cases on this map. Each measurement is indicated by a line in the direction of the E-vector, proportional in length to the degree of polarisation, and centred on the point observed. The map is superimposed on a photograph of M104. The polarisation in the dark lane has an average value of $2.2 \pm 0.5\%$ and position angle of $86° \pm 5°$. A previous single measurement in this area by Appenzeller[4] is in agreement with our values if we integrate over a similar area to that used by Appenzeller.

The main features of the polarisation map are: (1) An almost uniform polarisation parallel to and along the central dark lane spanning an area at least ~ 100 × 30 arc s, which at a distance of 12 Mpc (ref. 9) is equivalent to 6 × 1.6 kpc. The orientation of the polarisation is also maintained over the brighter part of the lower optical lens. (2) In the upper lens the electric vectors are perpendicular to the dark lane. The transition from parallel to perpendicular orientation of the electric vectors is abrupt.

In Fig. 2 we show the intensity (I) and polarised intensity (P) as functions of position along a scan line perpendicular to the dark lane and through the nuclear region. We note several

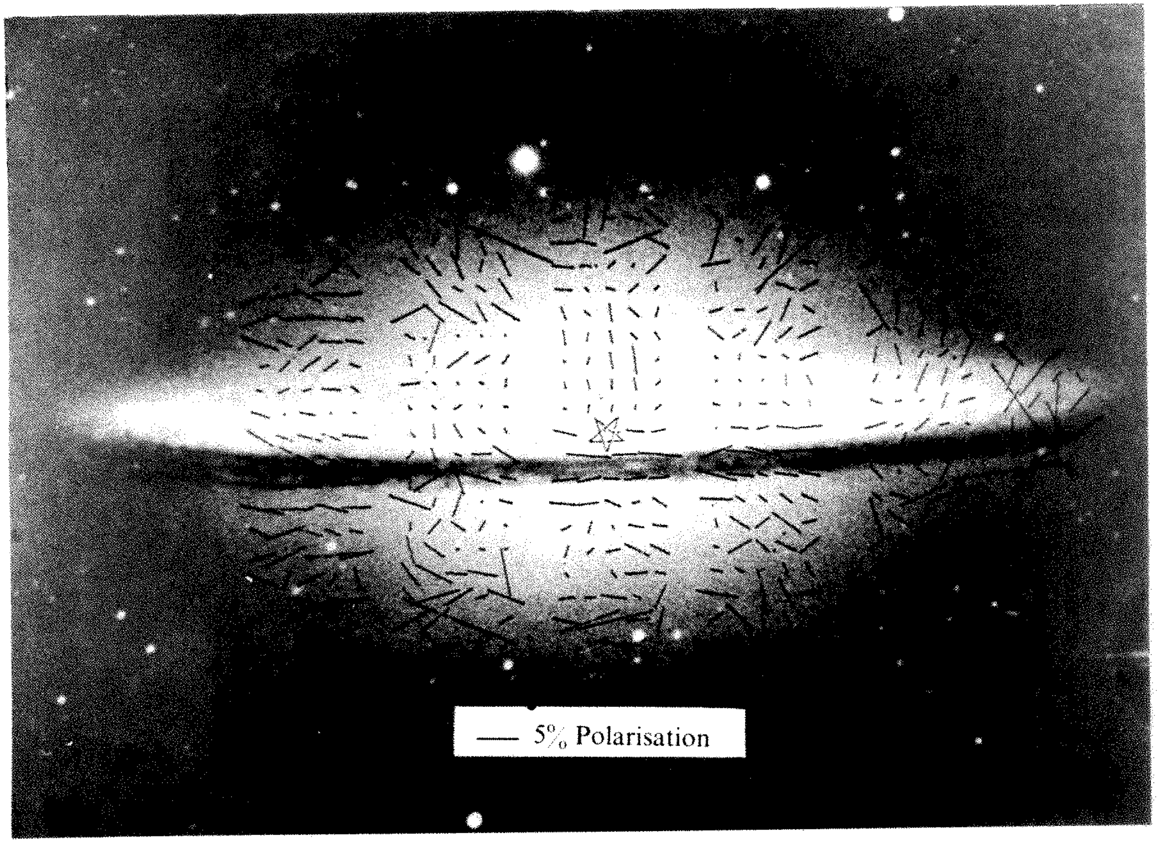

Fig. 1 The linear optical polarisation of M104 in the B waveband. *Represents position of nucleus.

features of the graphs. (1) The centre of the dark lane is readily apparent in the graph of *I*; it is at the pronounced dip and below the maximum of *I*. (2) The maxima of *I* and *P* are not coincident; the former maximises (I_{max}) at 21 arc s N of the dark lane and the latter (P_{max}) at 14 arc s N. (3) While neither *P* nor *I* is symmetrical about its maximum, *P* is more symmetrical. The change from parallel to perpendicular alignment of the **E**-vectors occurs between the maxima of *P* and *I*.

Finally we have integrated over the whole electronographic plate and estimate that the apparent nucleus contributes approximately 20% to the total luminosity.

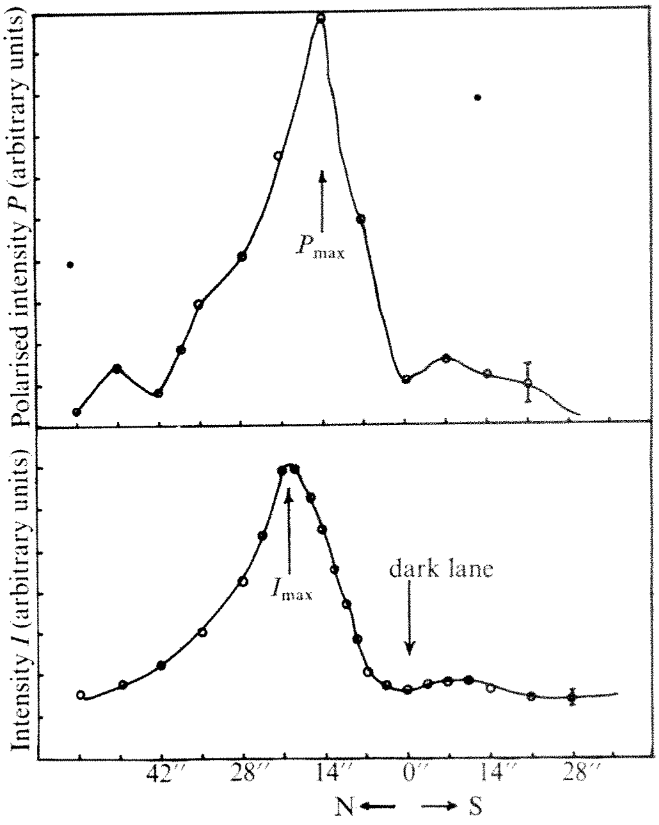
There is little doubt that the observed polarisation pattern is due to the scattering and extinction of light by statistically aligned dust grains. Synchrotron emission is eliminated as M104 is neither a radio[10] nor an X-ray source[11]. Rayleigh scattering can also be eliminated as the illumination of an optically thin Rayleigh atmosphere by a nucleus plus disk produces a distinctive centro-symmetrical pattern[7] quite unlike that observed.

The alignment of the dust grains is most probably due to magnetic effects as proposed by Davis and Greenstein[12]. The alignment in our Galaxy has been the subject of much discussion; radiative transfer of angular momentum by optical[13] and X-ray[14] photons and gas streaming[15] are alternative processes to the Davis–Greenstein effect for dust alignment. However, it is difficult to see how the alternatives could be effective in the case of M104 as the optical photons would produce alignment in the wrong sense to that observed; for gas streaming the alignment would be slowly changing with no polarisation observed at the outer edge of the disk: this again is not observed. Thus unless some heretofore unexpected mechanism is at work the grains must be magnetically aligned.

The change in orientation of the polarisation vectors from perpendicular to parallel to the dark lane is probably the result of increasing dust density towards the plane of the galaxy and a corresponding change of polarisation by scattering to extinction. This then implies that the magnetic field maintains its orientation not only for another 2 kpc above the galactic plane but in depth as well.

The condition for the transition in orientation is that the polarised intensity from scattering (P_s) of disk light must exceed the polarised intensity from extinction (P_e) of halo starlight beyond 21 arc s above the dark lane. Since light scattered by aligned dust grains[16] (submicrometre prolate spheroids) is polarised by some 50% (for scattering optical

Fig. 2 Graphs of the intensity and polarised intensity for a scan in the N–S direction through the central region of M104.



depth $\tau_s < 1$) we have $P_s \approx 0.5\ \tau_s L_D/4\pi h^2$ where L_D is the galactic disk luminosity (nucleus included) and h is the height above the disk. P_e is given by $P_e \approx 3.10^{-2}\ e(-\tau_e) n_* L_* Z/4\pi$ where n_* and L_* are the density and luminosity of halo stars, Z is the line of sight distance through the halo, and τ_e is the optical depth for extinction. A polarisation of 3% is assumed for extinction. For $P_s > P_e$, one has

$$\tau_s L_D > 0.1(1-\tau_e)L_H$$

where $L_H \approx n_* h^2 Z L_*$ is the total luminosity of halo stars in the volume $h \times h \times Z$. Since $L_D > L_H$, this condition is easily satisfied far above the disk.

As h decreases however, the densities of both dust and stars increase, and stars which were illuminating dust above the galaxy begin to contribute to L_H, with a corresponding decrease in L_D, so that extinction begins to dominate. For low values of τ_s, small changes in n_* and $\tau_e \approx \tau_s$ can change the character of the polarised light completely, and this transition is what one observes 21 arc s N of the dark lane's centre. Evidently, the condition is not satisfied in the southern hemisphere of the galaxy, and extinction predominates.

From the fact that the I_{max} and P_{max} are not coincident, we infer that the brightest parts of the nucleus and disk are obscured. In fact, it seems that the (obscured) brightest part of the galaxy is between 7 arc s and 14 arc s N of the dark lane centre, near where P_{max} occurs. Here the optical depth τ_e must be larger than one, so that over some 14 arc s, τ_e varies by about two or three orders of magnitude. This implies a scale height of 100–200 pc for the dust, which is a typical galactic scale.

The fact that scattering from aligned grains is occurring makes M104 a likely candidate for observation of circular polarisation. If recent calculations[16] are applicable, then a circular polarisation of some 15% is introduced in the scattered light, which means we expect some 0.7% circular polarisation to be observable after dilution by halo starlight. The maximum degree of circular polarisation should be in the halo, but since the optical depth is large in the dark lane, the maximum absolute amount may be observed there. An observation of circular polarisation would tend to confirm our interpretation of the linear polarisation.

We have presented here our preliminary results, and fuller analysis and detailed models will soon follow. It seems, however, that we are seeing the most extensive homogeneous magnetic field observed so far and it is tempting to speculate that it may be primordial in origin.

We thank the Wise Observatory of Tel Aviv University and the Smithsonian Foundation for the use of their facilities in Israel and the Science Research Council for support. One of us (A.B.S.) was an SRC Visiting Fellow while the work was performed and thanks the Physics Department at the University of Durham for its hospitality. T. F. Carty and H. G. Perkins are acknowledged for their help in taking the data in Israel. Dr R. G. Bingham is thanked for his assistance on the project and in the interpretation of the data.

Verification by Viking Landers of earlier radio occulation measurements of surface atmospheric pressure on Mars

UNTIL this year, the most accurate means of studying the atmospheric pressure at the surface of Mars were provided by remote sensing from fly-by or orbiting spacecraft. Radio occultation, which involves observations on Earth of the effects of refraction on the radio link from the spacecraft in the Martian atmosphere, has been used repeatedly to measure the pressures and temperatures in the atmosphere of Mars from the US Mariner[1] and Soviet Mars[2] spacecraft. By far the largest number of these measurements, some 260, was obtained with the Mariner 9 orbiter in 1972–73[3].

The landing of Viking 1 in Chryse Planitia on July 20, 1976 provided the first opportunity to obtain measurements of atmospheric pressure directly from the surface of Mars. In the interest of comparing and verifying radio occultation results relative to the Viking *in situ* measurements, a computation was carried out to predict the atmospheric pressure at the landing site before the landing itself.

Because no radio occultation measurements existed near the Viking 1 site (22.3°N, 48.0°W), it was necessary to have a means of obtaining the relative altitude between occultation points and the Viking 1 site. This link was provided by Earth-based planetary radar data taken in 1967 (ref. 4), covering Martian latitudes from 19°N to 24°N. Four Mariner 9 occultation points lying within these latitudes were used to compute the distance from the centre of Mars (radius) of the zero-elevation reference level of the radar elevation profile (ref. 4, Fig. 4). These were points 77*N* (20.8°N, 337.7°W), 78*N* (24.1°N, 154.7°W), 418*N* (24.9°N, 180.9°W), and 420*N* (22.0°N, 172.4°W). The number designating the occultation measurement refers to the number of the revolution of the orbiter about Mars, and *N* stands for a measurement taken during entry into occultation. Combining the radii measured at those four points with the elevations indicated by the radar profile yielded a zero-altitude radius of $r_0 = 3389.54 \pm 1.5$ km. The uncertainty was estimated on the basis of uncertainties in both the radar and occultation measurements.

The predicted pressure at the Viking 1 site can then be estimated either with reference to a 6.1-mbar areoid computed from the gravity field of Mars and Mariner 9 occultation data[5] or by direct comparison with occultation points consistent with the areoid. The results are displayed in Table 1.

The quantity Δh is the altitude difference between the Viking 1 landing site and the 6.1 mbar areoid in the first instance, and the radii measured at the respective occultation points in the second two. These are then used, assuming a 12-km scale height (corresponding to the expected atmospheric temperature at the time of Viking 1 landing) to extrapolate the pressures shown in the column labelled 'source' to the pressure at the Viking 1 site, which is given in Table 1, column 3.

These estimates of pressure are valid for the season of Mariner 9 measurements. Because of the interaction of the atmosphere of Mars with the polar caps, however, the global atmospheric pressure is expected to vary over a Martian year by as much as 1.7 mbar[6]. Although much uncertainty is attached to these estimates of seasonal variation, which will be definitely established by Viking measurements, it was estimated that the pressure should be lower by about 0.2 mbar at Viking 1 arrival relative to Mariner 9. This correction was made, and the corrected figures appear in Table 1, column 4. Finally, an average of the three determinations was taken, yielding a prediction of 7.6±1.1 mbar.

The mean diurnal atmospheric pressure actually measured by Viking 1 was 7.65 mbar by the meteorology experiment[7] and 7.3 mbar by the entry science experiment[8].

The near exact correspondence of the measured and predicted pressure is of course fortuitous in view of the 1.1-mbar uncertainty attached to the prediction. Nevertheless, it indicates that the radio occultation results from Mariner 9 closely correspond to the actual surface pressure on Mars, which should enhance the credibility of the radio occultation method and of results obtained from planets and satellites whose atmospheres have not been directly probed.

Table 1 Estimates of pressure

Source	Altitude difference Δh (km)	Pressure at Viking 1 site (mbar) Mariner 9 season	Viking 1 season
Areoid $p=6.1$	-2.93 ± 1.5	7.8 ± 1.0	7.6 ± 1.0
Occ. pt 420N $p=6.7\pm0.5$	-2.46 ± 1.5	7.5 ± 1.1	7.3 ± 1.1
Occ. pt 78N $p=7.65\pm0.5$	-0.67 ± 1.5	8.1 ± 1.2	7.9 ± 1.2
Average, corrected for season			7.6 ± 1.1

A more cursory prediction was made for the Viking 2 landing site (48.0°N, 225.7°W). In the absence of planetary radar data, a Mars contour map compiled from Mariner 9 data[9] was used to obtain altitude differences, and less reliable extended mission data were used. After correction for seasonal variations, a pressure of 6.7±1.4 mbar was predicted. The actual pressure as measured by the meteorology experiment (unpublished data) was 7.72 mbar, within the uncertainty bounds of the prediction.

This work was carried out under a NASA contract.

Search for superheavy elements in monazite by Rutherford backscattering

EVIDENCE that superheavy elements with $Z=116$, 124 and 126 may exist in monazite inclusions associated with giant haloes in biotite mica has recently been reported[1]. As there is no evident reason why such elements should not also exist elsewhere, it would seem fruitful to search for superheavy elements in monazite inclusions not associated with giant haloes, or even in bulk monazite, although their concentrations in such environments may be considerably lower than in giant halo inclusions.

In this letter, we report the results of such a search in samples of bulk monazite by a technique capable of detecting concentrations of order 1 p.p.m. A beam of ^{32}S ions is Rutherford scattered[2] backwards from the sample and the energies of the scattered ions are measured. The energetics of the scattering process are described by classical mechanics; at exactly 180°, for example, the energy of a particle of mass m and incident energy E_i scattered by a nucleus of mass M is just $E_{sc}=((M-m)/(M+m))^2E_i$ for $M>m$; if $M<m$ no scattered events will be observed and this is the case for all angles greater than 90°. As the target mass M increases, so also does the energy of the scattered particle. With the incident energy known, a measurement of the scattered energy can therefore be used to deduce the mass of the target nucleus.

We have used beams of 42 MeV ^{32}S ions from the Oxford Tandem van de Graaff accelerator to bombard targets of monazite sand obtained from the mineralogical collection of the University Museum and originating from India. The sand was finely powdered and glued on to aluminium backings; the resulting monazite targets were sufficiently thick (several mg cm^{-2}) to stop the beam. No backscattered events from the aluminium or from the constituents of the organic glue can occur because these elements are lighter than sulphur. The scattered sulphur ions were detected at a mean angle of 165°, the largest angle at which our detectors could be placed without interfering with the incident beam. Two thick silicon surface barrier detectors (50 μm and 75 μm) were used on opposite sides of the beam. The primary constituents of monazite, essentially (Ce, La, Y, Th) PO_4, which can scatter sulphur ions into the backward hemisphere are the lanthanides (mainly Ce and La), Th and U. The phosphorus and oxygen are again lighter than sulphur and thus will not contribute. In the Table, we give the maximum energies of the backscattered sulphur ions from these and a possible superheavy constituent, under the experimental conditions mentioned above.

The energy spectrum of backscattered sulphur ions obtained from a 10 h exposure with one of the detectors is shown in Fig. 1. (A similar spectrum was obtained with the other detector.) Notice that the vertical scale is logarithmic, but with zero included; energy is plotted along the horizontal axis. The sharply cut off edges correspond to the maximum scattered energy from each of the elements indicated; i.e. from the target surface. The plateaux extending down to zero energy are due to the fact that the incident or scattered ion beam can lose all or part of its energy in the target.

If elements with $A>238$ are present, then scattering from such nuclei would give rise to events above the Th+U edge (Table 1). Figure 1 shows the position of the edge corresponding to $A=354$ which is a predicted mass number for the most stable isotope of element 126 (ref. 3). However, such events can also arise from 'pile-up' caused by the simultaneous detection of two (or more) pulses of lower energy, and this limits the sensitivity of the technique. In

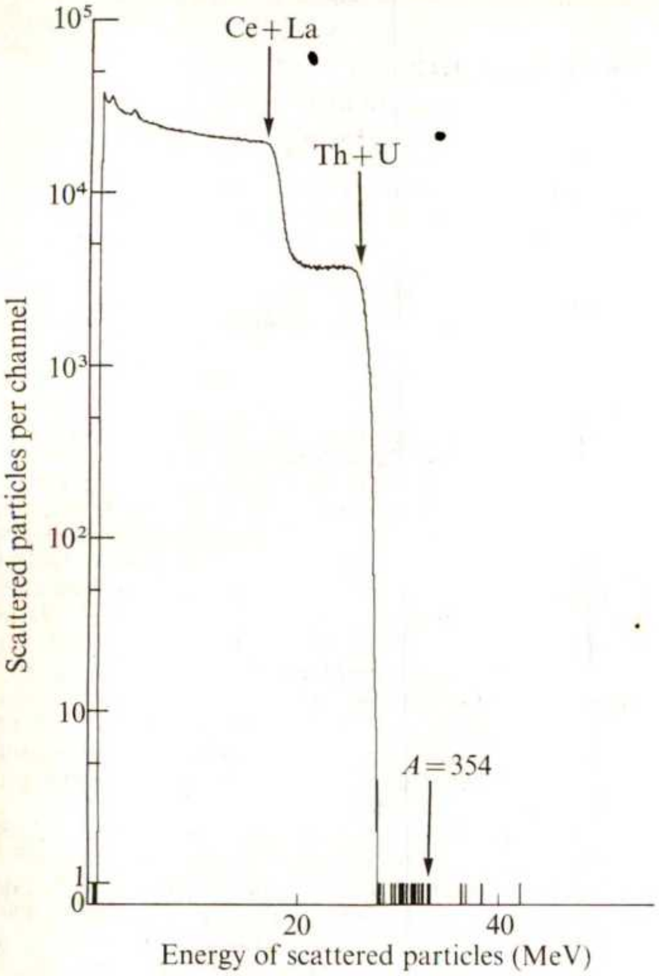

Fig. 1 Energy spectrum of ^{32}S ions of incident energy 42 MeV scattered from a target of powdered monazite sand observed at an angle of 165°. The edges correspond to scattering from the various constituents of the target (see text). An energy of ~24.5 MeV corresponds to channel 500 and there are an average of < 0.2 counts per channel in the region between the Th+U edge and the calculated position of the edge for $A = 354$.

the spectrum shown, there are 21 counts above the Th+U edge. Even under the improbable occurrence that these events were all due to scattering from superheavy nuclei, the level of the rare earths in Fig. 1 implies an upper limit of 2 atomic p.p.m. of superheavy nuclei of mass 354 (and approximate charge 126) relative to the concentration of the rare earths (mainly Ce and La) in our sample, where the Z^2 dependence of the Rutherford scattering cross section has been taken into account. (An analysis of the spectrum obtained with the other detector gave an upper limit of 1 atomic p.p.m.).

By using heavier projectiles than sulphur (for example, iodine or uranium) this limit might be reduced by a significant factor. A uranium beam is particularly attractive as only scattering from target nuclei with $A>238$ can contribute to the spectrum of scattered particles observed at angles greater than 90°. Such beams may well permit the detection of superheavy nuclei, if they exist, at very low concentrations indeed.

Table 1 Calculated energy of ^{32}S ions, incident energy 42 MeV, with observation at 165° after scattering from various heavy constituents of monazite

Element	Mass number	Energy (MeV)
Ce	140	16.81
Th	232	24.33
U	238	24.67
(126)	354	29.40

A value is included for a possible superheavy element with mass 354.

We thank Dr F. B. Atkins, Curator of the Mineralogical Collections of the University Museum for the provision of the monazite and Dr M. A. Grace and Dr H. J. Rose for valuable suggestions.

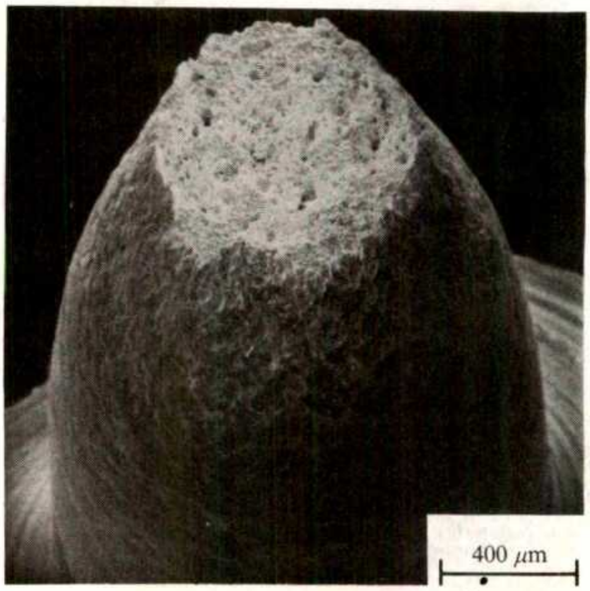
Cadmium metal embrittlement of Zircaloy-2

EFFECTS of chemical environments upon the mechanical properties of zirconium alloys are of great interest because such alloys are used to contain fissionable fuel in water-cooled nuclear reactors. Particular interest attaches to stress corrosion cracking or liquid metal embrittlement because both of these phenomena are known to produce non-ductile fractures in otherwise ductile materials. Rosenbaum *et al.* reported iodine stress corrosion cracking of Zircaloy-2 some years ago[1,2], and this phenomenon has been extensively investigated by others[3–5]. Zircaloy-2 is an alloy of zirconium containing by weight about 1.5% tin, 0.15% iron, 0.1% chromium, 0.05% nickel and 0.12% oxygen. Cox has reported embrittlement of Zircaloy by mercury or liquid caesium at room temperature[3]. However,

Fig. 1 Scanning electron micrograph of a fracture surface of Zircaloy-2 broken in caesium at 300 °C; elongation rate 2×10^{-3} inch min^{-1}, sample guage length 0.13 inch.



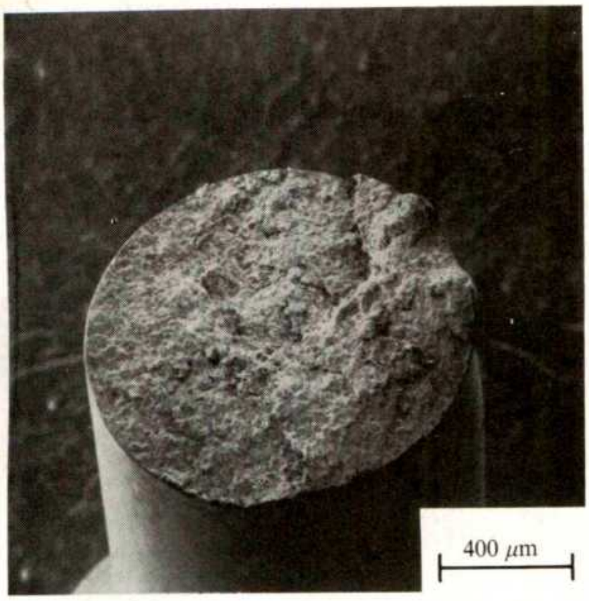


Fig. 2 Scanning electron micrograph of a fracture surface of Zircaloy-2 broken in caesium saturated with cadmium at 300 °C; other conditions as in Fig. 1.

the phenomenon of liquid metal embrittlement is known to be favoured by low temperatures[6], and Zircaloy nuclear fuel cladding operates in the vicinity of 300 °C.

It is the purpose of this note to report the observation of embrittlement of Zircaloy-2 in the temperature region of 300-340 °C by cadmium. Embrittlement occurred in the presence of solid cadmium at 300 °C, liquid cadmium at 340 °C, or cadmium dissolved in liquid caesium at either temperature. On the other hand, caesium alone did not embrittle Zircaloy-2 over this temperature range. Embrittlement of titanium alloys by solid or liquid cadmium has been reported by others[7–9].

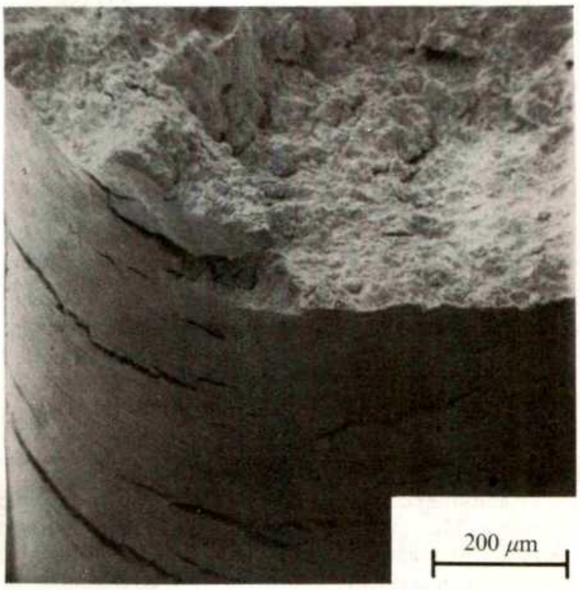

Fig. 3 A portion of the sample of Fig. 2 showing side cracks.

Figures 1, 2, and 3 show fracture surfaces of samples broken in caesium (Fig. 1) or caesium saturated with cadmium (Figs 2, 3) at 300 ± 10 °C. The fracture in caesium occurred with a reduction of area of about 75% and shows a typical ductile morphology similar to that observed in an inert argon environment. The fracture in caesium plus cadmium occurred with substantially zero reduction of area, and the fracture surface seems non-ductile. A portion of that surface at higher magnification is shown in Fig. 4. The mode of fracture is clearly transgranular with quasi-cleavage faces. It is, in fact, similar in appearance to fracture surfaces obtained by breaking Zircaloy-2 in iodine vapour at 300 °C (ref. 3).

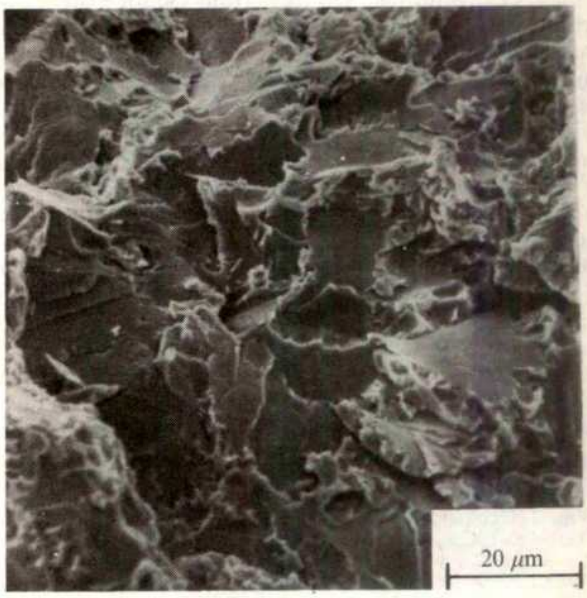

Fig. 4 A portion of the fracture surface of Fig. 2 at high magnification.

The tensile samples of Figs 1–4 were smooth-bar samples cut in the thickness direction from cross-rolled Zircaloy-2 plate. The plate was prepared according to a mechanical schedule described by D. Lee[10] to provide a high degree of orientation of the *c* (0001) axis in the thickness direction. Cracks caused by cadmium seem to occur along or near the basal plane perpendicular to the *c* axis and the applied stress axis, as Figs 2 and 3 show.

These results seem to be the first observation of cadmium embrittlement of Zircaloy-2. I am investigating the phenomenon further; the experimental techniques and further results will be reported in the near future.

I thank Morris H. Morgan III for experimental assistance, D. Lee for samples and advice on cross-rolled Zircaloy, and A. W. Urquhart for discussions.

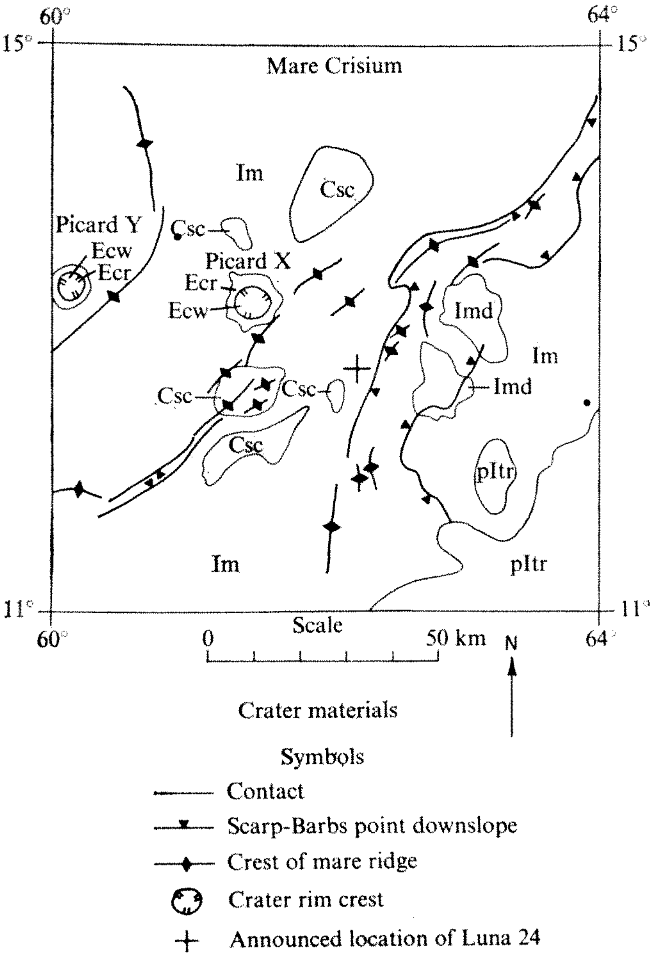
Age of Luna 24 mare basalts based on crater studies

THE recent return of regolith material from Mare Crisium by Luna 24 has provided an opportunity to test our knowledge of lunar impact-flux history. This can be done by comparing crater density data for the landing site with a calibrated impact flux curve to estimate the absolute age of the sample before chemical analysis.

Luna 24 returned samples from south-eastern Mare Crisium (12.7°N, 62.2°SE). The area around the landing site was mapped (Fig. 1) in detail from Apollo panoramic photographs. Obvious swarms of secondaries and endogenic craters were excluded from the crater counts and only one unit was counted at a time. This was to ensure that only the crater (production) population was counted for a single unit. Two major mare units occur in the mapped area; Imbrian mare (Im) on which Luna 24 landed, and dark (low albedo) Imbrian mare (Imd). An additional mare unit may be present just north of the mapped area according to the data of Neukum, König, and Arkani-Hamed[1]. Crater counts were made in two areas, one containing 2,920 km^2 (120 craters counted) of unit Im (including the landing site) and the other 256 km^2 (37 craters counted) of Imd, using Apollo panoramic and metric photographs. Diameter-cumulative frequency curves were constructed from these crater counts. These curves are shown in Fig. 2. C_s (ref. 2), the intersection of Trask's[3] steady-state curve and the extension of the approximately −3 slope crater production curve, is also shown in Fig. 2 for each of the three major mare units in and around the Lunar 24 landing site and the six Apollo landing sites[1-7]. The location of C_s values (which are a measure of impact flux) shows that the Luna 24 landing site is more densely cratered than the Apollo 12 and 15 sites, and less cratered than the Apollo 11, 17, 16 and 14 sites. C_s values for the Apollo landing sites can be compared with Apollo radiometric ages[7-11] to establish the lunar impact-flux history. This curve is shown in Fig. 3 and can be used to estimate the age of the Luna 24 site which is about 3.5 Gyr with a probable error of ±0.1 Gyr. Since the returned sample is of regolithic materials it could also contain basalt fragments which have been transported into the area by impact from the other nearby units. Although this is unlikely, there may be basaltic fragments from the other two units included in the Luna 24 core that are about 3.75±0.1 Gyr (Imd) and 2.5±0.3 Gyr (northern unit).

Fig. 1 Geological map of the Luna 24 landing site. Crater Materials: Csc, Copernican secondary craters; Ecw, Eratosthenian crater wall; Ecr, Eratosthenian crater rim (hummocky facies). Other materials: Im, Imbrian mare; Imd, Imbrian mare dark; pltr, pre-Imbrian terra rugged.



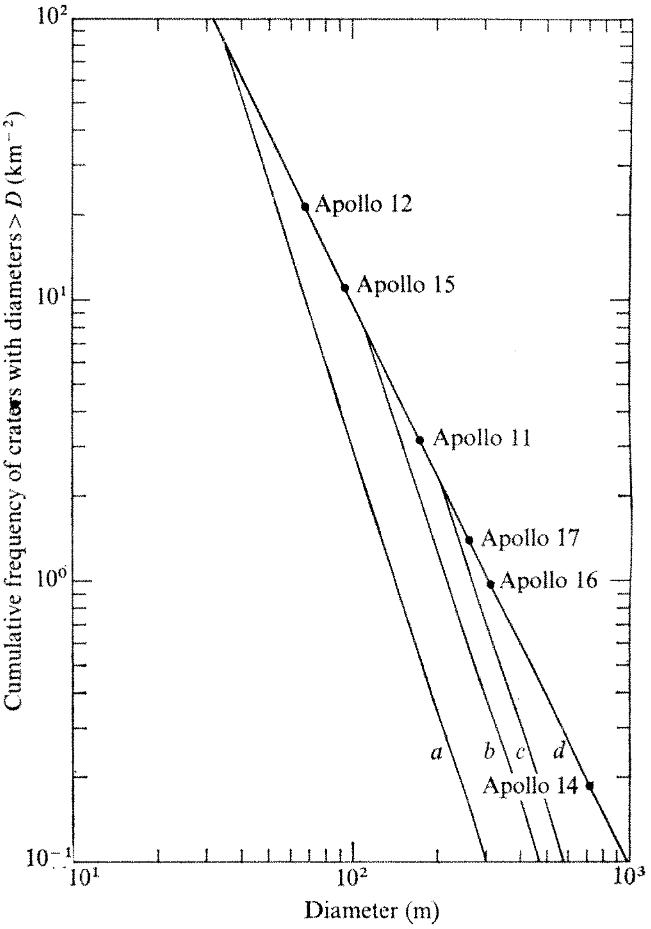


Fig. 2 Cumulative size frequency of craters on the three major mare units (Im, Imd, and the northern unit) in the vicinity of the Luna 24 landing site. The curves are extended to the steady-state curve of Trask's[1] to obtain the C_s values for each curve. C_s values for each Apollo landing site are also included for comparison. *a*, Luna 24 northern unit; *b*, Luna 24 landing site (Im); *c*, Luna 24 (Imd); *d*, $N = 10^{1.9}D^{-2}$.

Additionally, information about the geochemistry of the Luna 24 basalts can be determined from spectral reflectance measurements. Spectral reflectance data[13-15] indicate that most of southern Mare Crisium (including the Luna 24 landing site) is 'red' low-titanium basalt similar to that at

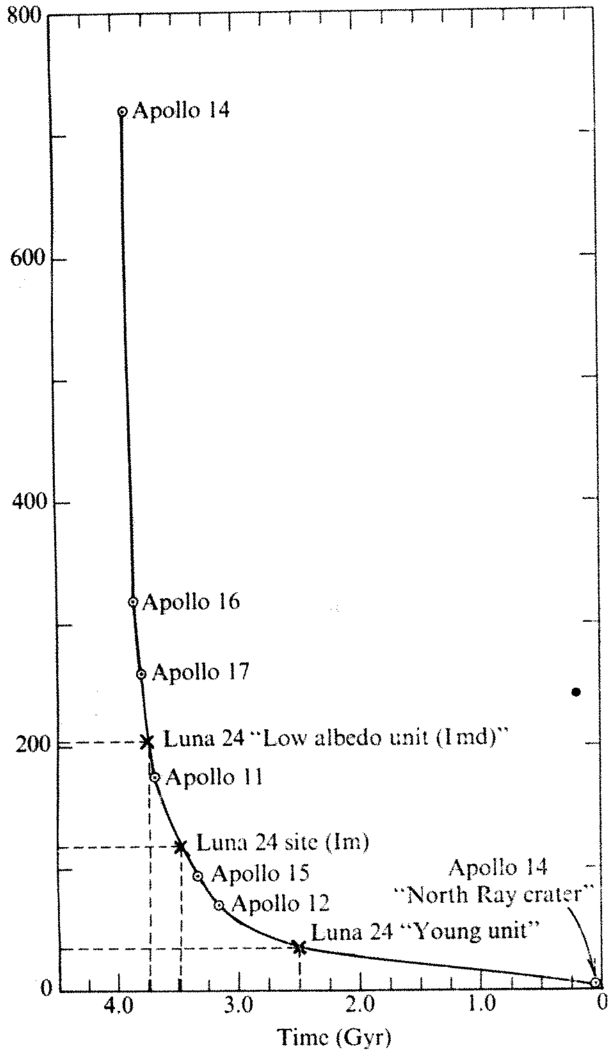

Fig. 3 Comparison of C_s values (a measure of impact flux and relative age) and crystallisation ages of Apollo samples. The estimated ages of the three units that may have been sampled by Luna 24 are included.

the Apollo 15 site. Therefore, based on crater frequency data and spectral reflectance data, we suggest that the mare basalts sampled by Luna 24 are similar in age and composition to those sampled by Apollo 15.

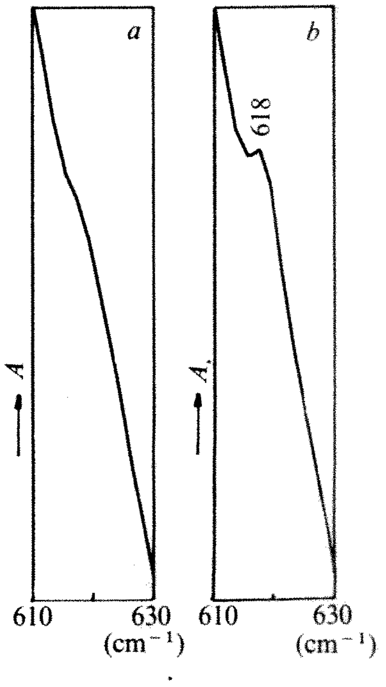
Polymorphic transition in silica glass

THE short range order in glasses is now more or less generally accepted to have a dimension of 20 Å or slightly more[1,2]. In the case of silica glass we have established[3], on the strength of infrared absorption bands, that those regions (clusters, substructures) have the high-cristobalite structure, which is metastable at room temperature and normal pressure. It has been possible to relax a polymorphic transformation in pure silica glass into the stable low temperature form of cristobalite by heating a powdered sample at 483 K for 27 h (ref. 3). Heating relaxed the existing strains in the clusters by adjusting their structure to the low temperature conditions. A report by Wagstaff[4] suggested another possible way of provoking the transition—by increasing the strains in the high-cristobalite clusters in silica glass by cooling it to liquid helium temperature.

Using the attenuated total reflectance (ATR) technique in infrared spectroscopy, we have proved that such a transformation takes place in experimental conditions, after a powdered sample of pure silica glass has been kept for several days at liquid helium temperature. No transition was observed in a piece of this glass kept in the same conditions, which agrees with the result of the heating experiments. The low-cristobalite form of silica shows a characteristic absorption band (618 cm^{-1}) which is absent in the regular high-cristobalite form[3]. This band provides an easy way of observing the transition process. Using powdered mixtures of pure silica glass and known quantities of crystalline low-cristobalite for an approximate calibration, we found about 1% conversion by weight of glass. This is a rather small amount of new phase compared with nearly 100% conversion reached in the heating experiments (but only in some of them). Nevertheless, we have obtained further evidence to confirm the possibility of provoking a

Fig. 1 ATR absorbance plots. *a*, Powdered silica glass before cooling at liquid helium temperature; *b*, the same sample after cooling.



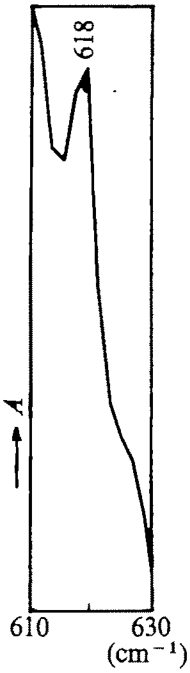


Fig. 2 ATR absorbance plot: computed ratio of Fig. 1*a* and *b* curves. All figures were drawn directly by the Digilab FTS-14 instrument.

polymorphic transition in X-ray amorphous substances, such as silica glass. Independent confirmation comes from the very sensitive thermal expansion observations on silica glass of C. F. Drake, referred to by C. H. Goodman[5].

We are also studying the heat effects of the transition. Preliminary experiments with very sensitive differential scanning calorimetry equipment also unequivocally point to the presence of partial polymorphic transition in silica glass at 542K. This work is still in progress. Thus evidence is accumulating to suggest that polymorphic transitions occur in regions as small as about 20 Å. This, at least in the case of vitreous silica, has also helped to establish firmly the structure of clusters, as polymorphic transitions are strictly characteristic for each form of crystalline silica.

The Digilab FTS-14 Fourier transform spectroscopic instrument was used in this work and appropriate computer programs were used to compare spectra obtained before and after cooling the same sample of glass.

We thank Dr Miroslaw Handke for help with the ATR measurements and Mr Edward Görlich Jr for the opportunity to do the liquid helium experiments.

Thermoluminescent dating of Lake Mungo geomagnetic polarity excursion

ARCHAEOMAGNETIC studies made by Barbetti and McElhinny[1,2] on prehistoric aboriginal fireplaces at Lake Mungo, Australia, indicate the occurrence of a polarity excursion about 30,000 years ago during which the geomagnetic field intensity increased to three times its present-day value; this main excursion was followed by a second one during which the intensity decreased to about one third of the present day value. This note reports thermoluminescent (TL) dating measurements that were carried out on fireplace material at the request of Dr M. F. Barbetti. Comparison of the TL dating with the radiocarbon ages[3,4] is of particular interest because geomagnetic intensity variations may be the dominant cause of long term distortion of the radiocarbon time scale[5–7]. The geomagnetic field gives the Earth partial shielding from cosmic rays, particularly from the lower energy, component that reaches only the upper atmosphere and is responsible for most of the radiocarbon production. If the geomagnetic intensity was lower than usual, then the production rate would have been higher and this would cause relevant radiocarbon dates to be too recent. In this comparison of TL and radiocarbon ages we have not, however, found evidence for a disturbance of the radiocarbon time scale caused by geomagnetic polarity excursions.

The samples were baked clay–sand ovenstones from fireplaces F6, F7, F8, F9, F12 and F14 (see refs 1 and 2 for description and location of these hearths and ovens). Initially we attempted to use the fine-grain dating technique[8]. Apparent ages in the range 30,000–50,000 yr were obtained but these were considered to be a substantial overestimate due to the presence of ('spurious') TL (not induced by radiation) in the natural glow curve; this was presumably a result of the deposited carbonate that was evident in the samples. Attempts to eliminate the spurious TL by washing in acid were not successful.

The results reported here were obtained using quartz grains in the size range 90–125 μm, extracted from the baked clay–sand matrix by magnetic separation and sieving. The procedures followed were those developed by Fleming[9] for dating quartz inclusions from pottery of the last two or three millennia, appropriately modified on account of the much greater age of the Lake Mungo fireplaces as outlined below and as will be discussed more fully elsewhere. After extraction the grains were etched in hydrofluoric acid in order to remove the outer layer of material that had been irradiated with alpha particles from uranium and thorium in the matrix. The natural TL, which was measured immediately after etching, is therefore that induced by the dose from beta, gamma and cosmic radiation received since the fireplaces were last used. The beta and gamma dose rates were evaluated from radioactive and chemical analyses of the samples and the surrounding material; a value of 15 mrad yr^{-1} was used for the cosmic dose rate. The total dose received since last heating (the archaeological dose) was evaluated by comparison of the level of natural TL in the 375 °C region of the glow curve with the (natural+artificial) TL from a second portion, the artificial TL being that induced by irradiation with a ^{90}Sr–^{90}Y beta source Studies of the TL growth characteristics of these samples indicated that it was not valid to make the assumption of linearity of TL against dose and an exponential fit to the data points was made instead of the usual linear fit; the exponential fit was of the form $(1-\exp(-x/B))$, where x is the dose and B is a constant for which the experimentally determined average value for these samples was 40 krad

Use of an exponential fit (rather than a linear one) gives archaeological doses, and hence ages, that are lower by about 18%. The primary reason for rejecting the use of a linear fit was the observation that (G_2-G_N) was on average 6% less than $2(G_1-G_N)$, where G_N is the natural TL, and G_1 and G_2 are levels of TL from portions of sample to which beta doses had been administered before any heating of the sample, and the beta doses being 4.8 and 9.6 krad respectively. The inadequacy of the linear fit was further indicated by direct observation of TL growth with

Table 1 Thermoluminescence and radiocarbon dates of ovenstones from prehistoric fireplaces

Sample	Archaeological dose (krad)	Dose rate (rad yr^{-1})	Predicted errors ($yr \times 10^{-3}$) Random	Systematic	Combined	TL date ($yr \times 10^{-3}$)	^{14}C date ($yr \times 10^{-3}$ (5,568-yr half life))
First excursion							
F7B	7.05	0.20	3.6	4.2	5.6	35.3	
F7D	6.05	0.20	2.5	3.2	4.1	29.5	30.8 ± 0.5
F7P	6.50	0.21	4.4	3.7	5.6	31.3	—
F8B	7.95	0.21	2.7	5.7	6.4	37.9	28.3 ± 0.4
F9D	7.00	0.22	4.1	3.8	5.7	32.0	—
F9J	7.60	0.23	4.1	4.2	5.8	32.3	27.5 ± 0.3
F12E	6.25	0.16	6.2	4.4	7.7	38.6	28.0 ± 0.4
			Weighted mean (TL)	=	33.5×10^3 yr		
			Standard error	=	1.3×10^3 yr		
			Predicted error (random and systematic)	=	4.3×10^3 yr		
			Average (^{14}C)	=	30.4×10^3 yr (5,730-yr half life)		
Second excursion							
F6	5.50	0.25	2.8	2.4	3.7	21.8	26.3 ± 0.5
F14P	6.50	0.21	1.7	4.1	4.4	31.4	None

The predicted error is at the 68% level of confidence and calculated as explained in ref. 10. The TL ages were evaluated on the basis that the form of the TL growth characteristic was the same for all samples.

dose using portions from which the natural TL had been drained by heating. These 'second-glow' growth characteristics were exponential in form, having a value of B of about 10 krad. This is substantially less than the value of 40 krad that corresponds to an exponential interpretation of the 6% difference between (G_2-G_N) and $2(G_1-G_N)$ mentioned above, but the higher value for B is preferred on the grounds that a change in growth characteristic often occurs when a sample is heated, particularly during the drainage of the natural TL.

The 6% difference between (G_2-G_N) and $2(G_1-G_N)$ is interpreted in terms of an exponential rather than in terms of a binomial because the former corresponds theoretically to the trapping model in which electron concentration in the conduction band is proportional to the dose rate and the TL traps are limited in number; this is the next simplest model to the one that corresponds to linear growth. It is also to be noted that the binomial function predicts a maximum in the growth characteristic rather than saturation and, to the extent that the second-glow growth characteristic can be used as evidence, this is in strong contradiction with observation.

The data are given in Table 1. The measurement precision for these samples was rather poor and the scatter in the ages is not much greater than the scatter to be expected if the samples were all of the same age. Because of this an average TL age has been evaluated for the seven samples which are considered to be associated with the first polarity excursion on the basis of radiocarbon dating (that is, F7, F8, F9 and F12). Using our standard form of citation for TL dates the date obtained for the first excursion is 35,000 b.p. (±1,300, ±4,300, OxTL 174a). The two error limits quoted, which are calculated on the usual basis[10,11], are respectively the standard error of the mean derived from the observed scatter of the individual ages, and the error predicted by taking into account all sources of uncertainty both random and systematic; the dominant contribution to the latter arises from uncertainty in the value of B.

This date is substantially more recent than the preliminary value quoted by Fleming[12] and it is not significantly different from the average of the radiocarbon dates that are available for these four fireplaces, having in mind that it is the second error limit that is relevant to this comparison, nor from the TL date of 30,400 b.p. quoted by Mortlock[13] for fireplace F7.

As regards the second excursion it should be noted that the TL date obtained for fireplace F6 is substantially different from the average date obtained for the first excursion (having in mind that between TL dates for similar contexts it is the random error limit that is relevant) but that it differs by less than two standard deviations (of the overall TL error) from the two radiocarbon dates for that fireplace. Fireplace F14, undated by radiocarbon, was assumed to be associated with the second excursion on the basis of its low intensity value; however the TL result does not support this interpretation.

Although the present work gives no evidence that these geomagnetic polarity excursions gave rise to distortion of the radiocarbon time scale the data do not exclude a major perturbation; for example, the difference of 3,100 years between the average TL age and the average radiocarbon age for the first excursion, athough within the TL error limit, could correspond to an atmospheric radiocarbon concentration 45% in excess of the level for AD 1850. However, the high geomagnetic field intensity associated with the first excursion, if global, would cause the atmospheric radiocarbon concentration to be in deficit, whereas it is only with the second excursion when the field was low that an excess would be expected.

We are grateful to Miss Sheridan Bowman for an important observation made in the course of subsidiary measurements on one of these samples and to the Nuffield Foundation for provision of equipment.

Evolution of Lake Abhé (Ethiopia and TFAI), from 70,000 b.p.

We summarise here the first continuous stratigraphic sequence for the late Quaternary of the African continent, derived from a detailed study of the evolution of an intertropical lake: Lake Abhé (11°N, 42°E) (Fig. 1). For the interval 20,000–0 b.p., this record complements and amplifies existing knowledge, and it also throws valuable new light on the preceding period. It provides evidence for important late Pleistocene climatic changes at the eastern end of the Sahel zone.

The results come from a multidisciplinary 5-yr project, and supporting detail is available elsewhere[1]. Analyses of diatom associations, which are sensitive indicators of ecological conditions, were carried out on 492 samples, and supplemented by convergent evidence from sedimentary facies and mineralogy. Seventy-five ^{14}C dates, derived from a 50-m core taken at the edge of the present lake (Fig. 1) and from stratigraphic sequences on the margin of the basin, provide a chronological framework with a high degree of reliability (Table 1).

Lake Abhé occupies a closed tectonic basin in the Afar (Fig. 1). The present lake ($350\ \mathrm{km}^2$) has a surface elevation of 240 m, and is currently shrinking. Only a few metres deep, it is hyperalkaline and rich in sodium bicarbonate[2]. Since it is situated at the downstream end of the perennial Awash River, which drops from a height of 2,500 m on the Ethiopian Plateau, the lake records climatic fluctuations in the Ethiopian highlands as well as in the Afar itself.

The main stages in the late Quaternary history of Lake Abhé are summarised in Fig. 2 and Table 1. Its Holocene record agrees in detail with findings from other parts of intertropical Africa[3,4]. Three (possibly four) lacustrine phases are evident. The early Holocene phase, Abhé IV, is the most important. A comparable transgression has been documented for several East African lakes[1,5-9] and along the entire southern margin of the Sahara[10-12] (Fig. 3). The Abhé IV sedimentary facies (Table 1) reflect very low turbidities, indicating that precipitation was abundant and evenly distributed through the year, as was the case throughout the Sahel zone[11,13,14]. In spite of this parallelism in rainfall, early Holocene water temperatures deduced from the diatom floras seem to have been higher in Lake Abhé and in the rest of East Africa[1,8,15] than in Chad and Mauritania (ref. 11 and B. Marciniak, personal communication). This may arise from the greater cooling of the Atlantic than the Indian Ocean during the late Wurm[16]. The brief but well defined regression ~8,000 b.p. in Lake Abhé can be connected with a fall in the level of Lakes Rudolf[5], Nakuru[5] and Chad[11] (Fig. 3) and with a change in the flow regime of the Blue Nile around 8,000–7,000 b.p. (ref. 10). It is followed by another transgression, Abhé V (Fig. 2) during which ecological conditions resembled Abhé IV although the deposits are more silty or clayey. The lake level began to fluctuate after 6,000 b.p. and fell rapidly from ~4,000 b.p. until the lake dried out. During late Holocene time, there were several minor fluctuations (Abhé VI, Abhé VII) but clastic deposits dominated. Productivity remained very low and has tended to zero during recent centuries. It is difficult to establish close correlations between Abhé VI or Abhé VII and the several minor humid phases apparent from other basins in intertropical Africa[1,3,5,11,17].

Data from Lake Abhé also confirm the existence of the hyperarid phase, synchronous with the European late Wurm, which affected intertropical Africa[1,3,6,11,12,18-23] and probably the whole intertropical zone[24-26] between 17,000 and 12,000 b.p. In the Abhé core, this arid episode is registered by a thick soil, while large debris fans formed on the basin flanks[27]. Between 17,000 and 10,000 b.p. Lake Abhé was dry.

The most important results of the Lake Abhé study relate to the period before 17,000 b.p., about which little is known in intertropical Africa. Previously, only isolated dates

Turbidity and productivity: S, strong; M, moderate; l ,low; ll, very low.

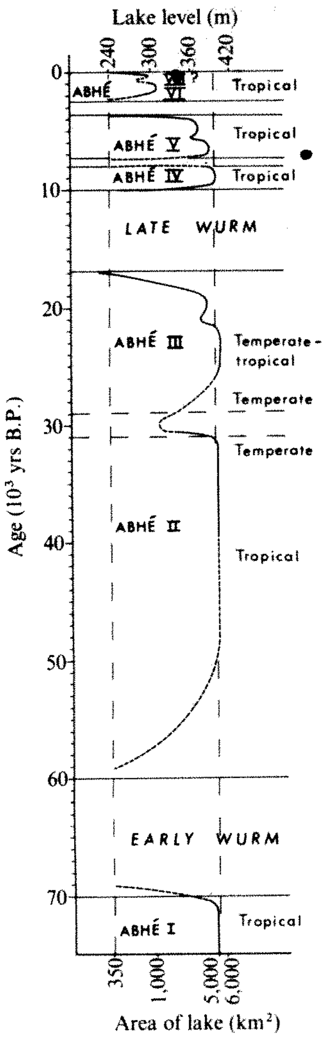

Fig. 2 Oscillations in the level of Lake Abhé from late Pleistocene to Holocene times. Based on 45 radiocarbon dates of littoral deposits for the period 0 to 35,000 b.p., and on extrapolation of mean sedimentation rates measured in the dated section of the core for the period before 35,000 b.p.

indicated high lake levels between 20,000 and 40,000 b.p. in Lake Nakuru[5], Chad[11] and Mauritania[12]. Three lacustrine phases (Abhé I, Abhé II, Abhé III), separated by drier episodes, occurred during the late Pleistocene. The earliest (Abhé I) lies beyond the range of ^{14}C dating. By extrapolating from the upper part of the Abhé core, its base (50 m) is dated at 70,000–100,000 b.p. On the other hand, the dry phase between Abhé I and Abhé II strongly resembles the arid 17,000–10,000 b.p. interval, so that it may correspond to the early European Wurm, dated by extrapolation from deep-sea cores to 60,000–70,000 b.p. (ref. 28). Abhé II began before 40,000 b.p. and was terminated by a minor regression around 31,000–30,000 b.p. (Table 1). The third phase, Abhé III, is dated between 30,000–29,000 b.p. and 17,000 b.p.

These three lacustrine phases were of similar importance (Fig. 2) but they strongly differed in their physico-chemical attributes (Table 1). The Abhé I lake was warm, alkaline, and clastic sedimentation predominates. The succeeding arid phase is marked by fluvial sands and gravels in the Abhé core and by debris fans on its margins. Abhé II was an episode of biochemical sedimentation. The lake received only material in solution, which implies gentle, well distributed rain and/or a dense vegetation cover in the catchment area. The diatom flora indicates a very warm, transparent lake with high alkalinity and productivity. Synchronous with the minor regression towards 30,000 b.p., the change in sedimentary facies was accompanied by a clear decrease in water temperatures and productivity, registered by the spread of cosmopolitan and temperate species. During the phase Abhé III, clayey calcareous diatomite accumulated in the lake. Temperate conditions persisted until 25,000 b.p. But tropical diatoms, which could support cooler temperatures than the Abhé II flora, multiplied again between 25,000 b.p. and 20,000 b.p. The ecological conditions then began to fluctuate. Numerous carbonate horizons were precipitated and brackish flora developed. The lake dried up ~17,000 b.p.

The late Quarternary evolution of Lake Abhé reflects changing precipitation–evaporation patterns. It is not yet possible to disentangle the relative effects of temperature and precipitation changes during the lacustral phases. But the episodes of greatest cold were definitely characterised by

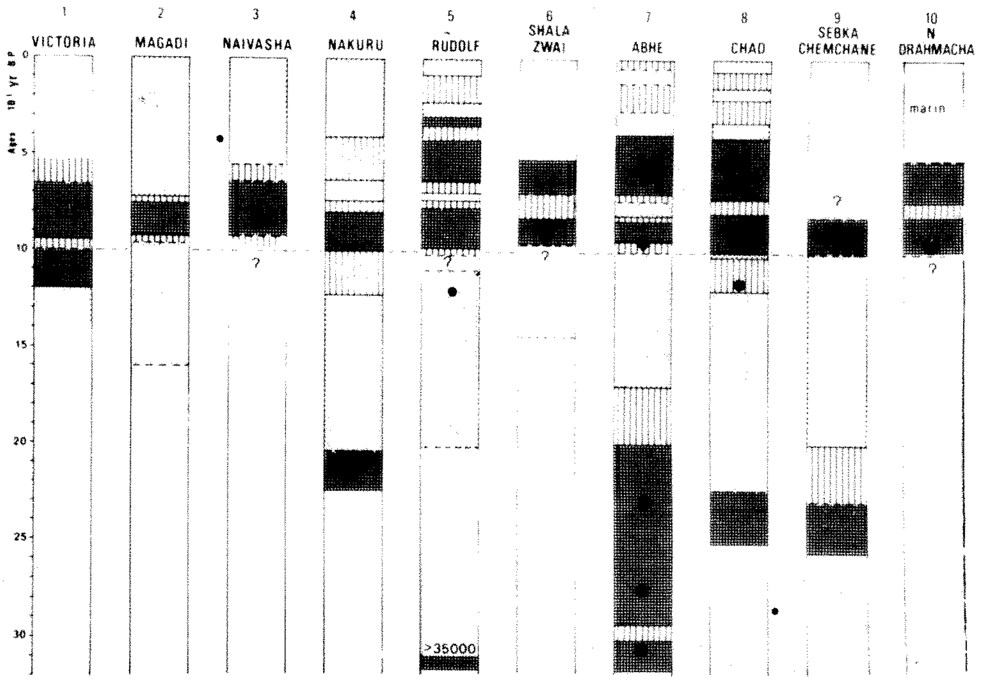

Fig. 3 Comparison between late Quaternary fluctuations of selected intertropical African lakes. From left to right the lakes grouped in order of increasing latitude (Lake Victoria 0°, Sebka Chemchane 21°N). (1) to (5) taken from ref. 5; (6) ref. 9; (7) this work; (8) ref. 11; (10) ref. 12 and B. Marciniak, personal communication. ◆, Diatom flora indicating a climate at least as warm as the present day; ●, diatom flora indicating a climate cooler than the present day.

aridity and lake-level minima. It is clear that fluctuations in the tropical atmosphere were systematically related to the high latitude glacial–deglacial sequence.

Sulphur isotope abundance elucidate uptake of atmospheric sulphur emissions by vegetation

THE sour gas wells of Alberta form the basis of its sulphur industry. The well known Claus process is used, whereby part of the H_2S is oxidised to SO_2 which is in turn reacted with more H_2S to yield elemental sulphur. As a consequence, more than 1,200 t of sulphur per day are discharged into the atmosphere in Alberta, mostly as SO_2. Using sulphur isotope abundances, I have assessed the uptake of these emissions by vegetation.

The H_2S processed in Alberta is typically enriched in the heavier ^{34}S with δ^{34}S values ranging from + 5 to +30‰ (refs 1, 2) where δ^{34}S is defined in terms of the $^{34}S/^{32}S$ abundance ratio in meteoritic troilite as

$$\delta^{34}S(\text{‰}) = \left\{\frac{[^{34}S/^{32}S]\,\text{sample}}{[^{34}S/^{32}S]\,\text{meteorite}} - 1\right\} \times 1{,}000$$

In contrast, most Alberta soils have δ^{34}S values ranging from near 0 to −30‰ (ref. 3). Since these variations are many times the measurement precision (±0.2‰ or better), sulphur isotope abundances can be used effectively to assess the impact of the sulphur emissions on the Alberta environment.

The success of this approach is illustrated by data from the Ram River Area in Alberta where two sour gas processing plants are operational (Fig. 1). H_2S is recovered from at least two geological reservoirs by the industrial operations and the stack SO_2 has δ^{34}S values that vary from +20 to +25‰. The major peak in the δ^{34}S distribution for air in Fig. 1 thus corresponds to the industrial emissions. At a given sampling site, the atmospheric isotopic composition depends on the ratio of industrial to background sulphur oxides. The latter vary considerably in concentration and isotopic composition depending on the season, biological activity and contributions from other anthropogenic sources. The mixing ratios depend on site location and meteorological conditions. For these reasons, the histogram for air in Fig. 1 is not a sharp peak corresponding solely to the industrial emissions. The secondary peak in Fig. 1 near +11‰ will be discussed later.

Lichens (*Usnea* sp., Fig. 1) had an isotopic distribution which coincided closely with the major peak of the air. This shows that lichens take up sulphur from the air by direct pathways. One process is the interaction with the gaseous sulphur oxides. Another source is rain which has passed through sulphate formed by oxidation of the atmospheric SO_2 or dissolved particulate sulphate deposited on bark. Subsequent studies (unpublished) with *Usnea* and other genera have shown that interspecies isotopic variations are not greater than the range encountered within one species at a given site.

Upper mossy layers of the soil in this region have δ^{34}S values near +15‰, suggesting a considerable uptake of industrial emissions. Below this mossy layer (~1 cm), soil sulphur has δ^{34}S values near +2‰ indicating that moss effectively blocks the passage of sulphur compounds to the subsoil. Isotopic profiles from several soil types suggest that factors which promote penetration are lack of biological cover, net drainage and the length of time that the industrial source has been operational.

Although Fig. 1 shows that pine needles (*Pinus contorta*) had a sulphur isotope distribution of similar shape, this is shifted by

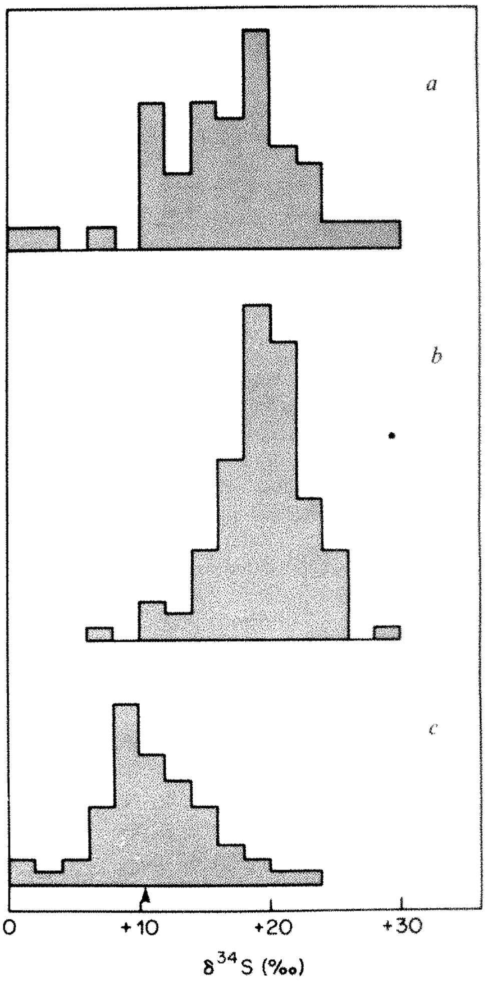

Fig. 1 Sulphur isotope variations in *a*, air; *b*, lichens and *c*, pine needles of the Ram River area for 1972–73. Atmospheric data were obtained from lead peroxide cylinders which had been set out for periods of 1 month to trap chemically the gaseous sulphur oxides. Lichens and live pine needles were gathered near the sites of the exposure cylinders. Their sulphur isotope data are based on all sulphur remaining after a brief ultrasonic washing with distilled water.

some 10‰ to lighter $\delta^{34}S$ values compared with those of air and lichens. In contrast to lichens and mosses, whose rhizines and rhizoids serve mainly for attachment, trees have root systems which transport sulphate upwards. Pine needles derive sulphur from both soil ($\delta^{34}S \sim +2$‰) and air (heavier $\delta^{34}S$ values) and therefore intermediate $\delta^{34}S$ values arise. Thus it might be argued that the data are not unexpected. But the isotopic technique facilitates assessment of the proportions of sulphur derived from the two sources. More recent data from a control site in the Ram River area, where the effects of the emissions were minimal, gave $\delta^{34}S$ values for needles and leaves similar to those of the soil ($\sim +2$‰). In another situation, sulphur compounds which originated with the industry had penetrated the soil to at least 40 cm and the conifer needles had $\delta^{34}S$ values near those of the ambient SO_2. At a given location under the influence of sulphur emissions, pine needles tend to have higher $\delta^{34}S$ values than spruce, indicating that the former derive proportionately more sulphur from the atmosphere. In the case of a very high *Pinus contorta* (~24 m) close to a sour gas processing plant (near Whitecourt, Alberta) an increase in $\delta^{34}S$ with height has been found, indicating that the canopy shields the undergrowth from the emissions.

Plots of $\delta^{34}S$ for lichens and needles compared with $\delta^{34}S$ values for atmospheric SO_2 are not as valuable for drawing conclusions as the histograms of Fig. 1. The chief reason is that the atmospheric data represent monthly averages whereas the times associated with the uptake of sulphur by lichens and needles are unknown. When certain growths can be correlated to a given period, there is no assurance that the rate of sulphur intake was uniform throughout that time. For these reasons my study lasted 2 yr in the Ram River area and needles and lichens were picked randomly near the air-monitoring stations. One concern is the extent to which the exposure cylinders are selective in the isotopes they take up especially because all field conditions are not readily simulated in the laboratory. Data obtained with high volume atmosphere sampling techniques under the auspices of the University of Calgary Interdisciplinary Sulphur Research Group (UNISUL) have been generally consistent with those obtained with lead peroxide cylinders (unpublished results). Although some of the data in Fig. 1 might have been shifted in extreme field conditions, lack of confidence in the more frequent values seems unjustified. In that the most frequent $\delta^{34}S$ values for the exposure cylinders and the lichens coincide, it would be necessary to postulate similar isotopic selectivities for both uptake mechanisms. This seems unlikely.

Several questions remain concerning the general mobility of sulphur compounds in vegetation. Pine needles can release sulphur compounds to the air and this may account for the secondary peak at +11‰ for the atmospheric data of Fig. 1, which almost coincide with the peak in the needle data. Another problem is the extent to which isotopic selectivity is involved in the uptake and release of sulphur compounds by trees. These problems are being investigated. This study was supported by the Aquitaine Company, the Atmospheric Environment Service of Environment Canada and the Canadian Forestry Service.

Polygamy and genetic equilibrium

POLYGAMY is the normal practice in indigenous African and Islamic populations. Recently Konotey-Ahulu[1] has claimed that polygamy may explain the persistence of some abnormal haemoglobins in these populations. The generally accepted view is that the maintenance of balanced polymorphism in these populations at the loci of the commonest hereditary erythrocyte defects is due to a lesser susceptibility of the heterozygote[2-7]. An examination of that claim using a mathematical model shows that polygamy can lead to an equilibrium distribution in gene frequencies only if the male heterozygote tends to acquire more wives than either homozygote—a condition that is shown not to be unlikely in African and Islamic populations.

We consider a pair of alleles A_1 and A_2 and suppose that the associated genotypes A_1A_1, A_1A_2 and A_2A_2 have frequencies Q_{11}, Q_{12} and Q_{22}, respectively, in the present population before selection ($Q_{11}+Q_{12}+Q_{22}=1$). We assume the population is so large that the effect of random fluctuation of gene frequencies may be neglected. The generations are non-overlapping. Suppose s_1 and s_2 are the premating selection coefficients against the homozygotes A_1A_1 and A_2A_2, respectively ($0 \leqslant s_1, s_2 \leqslant 1$), then the premating genotype frequencies (after selection) are

$$q_{11}=\frac{(1-s_1)Q_{11}}{W},\ q_{12}=\frac{Q_{12}}{W},\ q_{22}=\frac{(1-s_2)_2Q_2}{W}$$

for A_1A_1, A_1A_2 and A_2A_2, respectively, where W is a normalising constant chosen to make $q_{11}+q_{12}+q_{22}=1$.

To incorporate polygamy we assume further that a man with genotype A_iA_j may marry n wives simultaneously or one after the other at random with probability

$$R_{ij}{}^{(n)}\left(\sum_n R_{ij}{}^{(n)}=1\right).$$

Let ${}_{ij}P_{rs}{}^{(n)}$ denote the conditional probability that an A_iA_j man, who marries n wives, will have an A_rA_s child. ${}_{ij}P_{rs}{}^{(1)}$ shall be shortened to ${}_{ij}P_{rs}$ for convenience. Then it follows from the condition that wives are chosen at random that

$${}_{ij}P_{rs}{}^{(n)}=1-(1-{}_{ij}P_{rs})^n \tag{1}$$

$$Pr\ (A_iA_j \text{ man marries } n \text{ wives})=q_{ij}R_{ij}{}^{(n)} \tag{2}$$

The zygotic frequencies (before selection) in the next generation are then found to be

$$\begin{aligned}
Q'_{11} &= \frac{1}{T}\sum_{n=1}^{\infty}\Big[q_{11}R_{11}{}^{(n)}\,{}_{11}P_{11}{}^{(n)}+q_{12}R_{12}{}^{(n)}\,{}_{12}P_{11}{}^{(n)}+ \\
&\qquad\qquad + q_{22}R_{22}{}^{(n)}\,{}_{22}P_{11}{}^{(n)}\Big] \\
Q'_{12} &= \frac{1}{T}\sum_{n=1}^{\infty}\Big[q_{11}R_{11}{}^{(n)}\,{}_{11}P_{12}{}^{(n)}+q_{12}R_{12}{}^{(n)}\,{}_{12}P_{12}{}^{(n)}+ \\
&\qquad\qquad + q_{22}R_{22}{}^{(n)}\,{}_{22}P_{12}{}^{(n)}\Big] \\
Q'_{22} &= \frac{1}{T}\sum_{n=1}^{\infty}\Big[q_{11}R_{11}{}^{(n)}\,{}_{11}P_{22}{}^{(n)}+q_{12}R_{12}{}^{(n)}\,{}_{12}P_{22}{}^{(n)}+ \\
&\qquad\qquad + q_{22}R_{22}{}^{(n)}\,{}_{22}P_{22}{}^{(n)}\Big]
\end{aligned} \tag{3}$$

where T is a normalising constant chosen to make $Q'_{11}+Q'_{12}+Q'_{22}=1$. ${}_{ij}P_{rs}$ can be expressed in terms of these mating

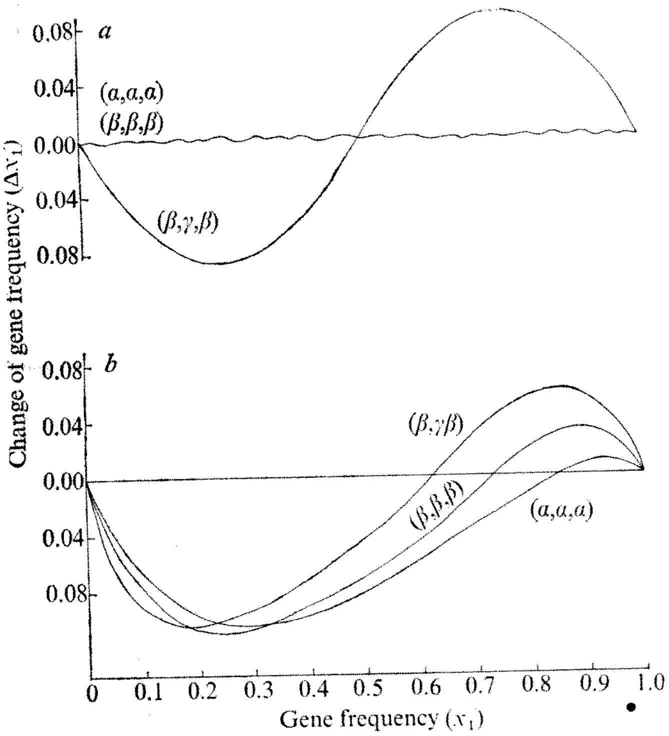

Fig. 1 Change in frequency of A_1, ΔX_1, at different values of the initial gene frequency X_1. *a*, No premating selection and no inbreeding, that is $s_1 = s_2 = F = 0$. *b*, $s_1 = 0.2, s_2 = 0.6, F = 0.1$. A graph marked (β, γ, β) refers to the situation where the conditional probability distribution of the number of wives are β, γ and β for A_1A_1, A_1A_2 and A_2A_2 men, respectively. ∝, β and γ are the hypothetical probability distributions below.

	Number of wives (n)	1	2	3	4	5	6	>6	Total
Probability distributions	∝	1	0	0	0	0	0	0	1
	β	0.5	0.3	0.1	0.06	0.02	0.01	0.01	1
	γ	0.1	0.13	0.17	0.40	0.18	0.01	0.01	1

∝: A_iA_j is monogamous; β: Half A_iA_j men marry one wife, the others marry more than one wife with decreasing probability; γ: Most A_iA_j men marry more than one wife, four being the commonest number of wives.

Note: (β, γ, β) describes the gene frequency changes for the situation where A_1A_2 has a greater probability than A_1A_1 and A_2A_2 to acquire many wives.

frequencies as shown in Table 1. So we can write Q'_{ij} explicitly in terms of the Q_{ij} values. The set of equations (3) then specifies the relationship between the genotype frequencies of any generation and that of the preceding generation. The form of equation (3) indicates that polygamy will not affect the behaviour of the system unless $R_{11}^{(n)}$, $R_{12}^{(n)}$ and $R_{22}^{(n)}$ differ. General solutions to the system could not be found. Some of the results of numerical calculations are illustrated in Fig. 1.

We note (Fig. 1*a*) that when there is no premating selection and no inbreeding, and every man marries one wife, every point is at equilibrium. This is consistent with the Hardy–Weinberg equilibrium law that a large population under random mating reaches an equilibrium no matter what the initial allelic frequencies may be. Other cases showed that polygamy will not produce a stable equilibrium in the absence of premating selective forces, except for the cases where the heterozygotes tend to acquire more wives than the homozygotes.

Our model is obviously oversimplified, but it does show that where the male heterozygote has a greater tendency to acquire more wives than either homozygote we can have non-trivial equilibrium at intermediate gene frequencies. This is in fact another form of differential selection in which heterozygotes are favoured over the homozygotes, and supports the hypothesis put forward by Fisher[8] to explain the phenomenon of balanced polymorphism. In effect, then, our model is equivalent to one in which selection operates differently in males and females as is the case with Owen's and Mandel's generalisation of it[9-11]. However, ours has the advantage of incorporating polygamy directly, and considers selection really in two stages: premating selection, and selection in the number of mates. This is important in the discussion on the maintenance of genes for abnormal haemoglobins in populations where malaria is endemic and polygamy is practised. Differential polygamy in which male heterozygotes show a greater fitness by virtue of their potentiality to acquire more wives, will enhance the effect of premating selective forces which favour the heterozygotes, in the maintenance of genetic variability in the population.

Table 1 Calculation of ${}_{ij}P_{rs}$

Man	Offspring	Wife A_1A_1 (q_{11})	Wife A_1A_2 (q_{12})	Wife A_2A_2 (q_{22})	${}_{ij}P_{rs}$
A_1A_1	A_1A_1	1	$\frac{1}{2}$	0	$q_{11} + \frac{1}{2}q_{12}$
	A_1A_2	0	$\frac{1}{2}$	1	$\frac{1}{2}q_{12} + q_{22}$
	A_2A_2	0	0	0	0
A_1A_2	A_1A_1	$\frac{1}{2}$	$\frac{1}{4}$	0	$\frac{1}{2}q_{11} + \frac{1}{4}q_{12}$
	A_1A_2	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}q_{11} + \frac{1}{2}q_{12} + \frac{1}{2}q_{22}$
	A_2A_2	0	$\frac{1}{4}$	$\frac{1}{2}$	$\frac{1}{4}q_{12} + \frac{1}{2}q_{22}$
A_2A_2	A_1A_1	0	0	0	0
	A_1A_2	1	$\frac{1}{2}$	0	$q_{11} + \frac{1}{2}q_{12}$
	A_2A_2	0	$\frac{1}{2}$	1	$\frac{1}{2}q_{12} + q_{22}$

In African and Islamic populations malaria is prevalent. The heterozygotes are therefore more likely to survive childhood than the normal homozygotes. These heterozygotes will tend to acquire more wives than the normal homozygotes because about half the children a heterozygous man has with a homozygous recessive woman will be homozygous for the unfavourable allele, and about one-quarter of the children he has with a woman who is heterozygous will be homozygous for the unfavourable allele. Most of the children homozygous for the unfavourable allele used to die very early and, since in African populations procreation is the *raison d'être* of marriage, the heterozygote would tend to marry more wives, in the hope that the children he gets with his new wives will 'stay'. Our analysis supports the view of Konotey-Ahulu[1] that polygamy could be one of the factors in the maintenance of the sickle gene in African and Islamic populations. It will enhance the effect of premating selective forces.

In our analysis we assumed hypothetical values for the probability that an A_iA_j man would marry n wives. The Ghana Institute of Clinical Genetics, Accra, is collecting data that would enable us to estimate these probabilities in African populations.

Lek behaviour in three species of the subgenus *Hirtodrosophila* of Australian *Drosophila*

LEK behaviour, or the use of courting territories, is well known in the patterned wing, Hawaiian species of the subgenus *Drosophila*, but not elsewhere in the genus[1]. Australian *Drosophila* comprise a major adaptive radiation in the subgenus *Scaptodrosophila*, and minor radiations in *Hirtodrosophila* and *Sophophora*[2,3]. We report here on three species of the subgenus *Hirtodrosophila*, two with patterned wings and one without, that show lek behaviour.

The species are found in rain forest habitats from eastern Victoria to northern Queensland, a latitude range of 37°S–16°S; floristic composition of the rain forests varies widely over this range[4]. In especially damp and shaded regions, however, bracket fungi (Polyporaceae) of various species occur, growing laterally from the sides of fallen logs or tree trunks close to the ground[5]. The three *Hirtodrosophila* species use the horizontal undersides of the fungi as leks. Males position themselves on the undersides of fungi at regular intervals; females from the surrounding vegetation occasionally land there, and courtship activities follow. The undersides of the fungi are white or light grey, strongly enhancing displays; flies have not been found on old fungi with dark undersides.

During courtship, wing display is prominent. Two species, *D. mycetophaga* and *D. polypori*, have patterned wings, and both are commonly found from eastern Victoria to southern Queensland (latitude 2°S)[3]. The third species, *D. mixtura*, however, occurs only in northern Queensland. Its wings are tinged brownish especially towards the costal margin, but in contrast to other Australian *Hirtodrosophila* species and the Hawaiian species, it is striking in appearance, being very dark above, and changing abruptly to unicolorous pale cream below. Like the patterned-wing species, therefore, flies stand out strikingly when displaying on the undersides of bracket fungi.

In addition, two other as yet undescribed and rarer species have been collected from under bracket fungi, one with patterned wings, and one very closely related to *D. mixtura*. Presumably, they too use the fungi as leks. It is remarkable that only three patterned-wing Australian *Hirtodrosophila* species are known, all apparently using the same defined courting territories.

The five species are somewhat larger than many other Australian endemic species[3]. In contrast to the Hawaiian patterned-wing species[1], sexual dimorphism has not evolved, except that males are somewhat smaller than females. A striking level of sexual dimorphism has presumably evolved in the Hawaiian species, because the advertising males occupy sites in foliage to attract females to these seemingly less well defined courting territories.

We conclude that two patterned-wing species in the southern part of Australia, and a non patterned-wing species in the north show lek behaviour, the leks being identical in type. Moreover Hawaiian lek species belong to the subgenus *Drosophila* suggesting that convergent evolution has occurred in two subgenera of the genus for a behavioural pattern of considerable evolutionary significance which is unreported elsewhere in the genus.

We thank the Australian Research Grants Committee (P.A.P.) and the Australian Biological Resources Survey (I.R.B.) for financial support.

Longevity and lifetime body weight in mice selected for rapid growth

AN association between lifespan and early growth rate as affected by nutritional manipulation has been reported; high intake–rapid growth apparently contribute to shorter lifespan, and low intake–slow growth to longer lifespan[1,2]. Genetically determined rapid growth has also been reported to be associated with shortened lifespan[3].

A strain of mice with approximately double normal growth rate, and with modified food intake, body composition and reproduction patterns has been developed by selection for body weight gain from 21–42 d of age[4]. We report here data on the lifespan and lifetime body weight of this strain (G) developed by us, and of contemporary animals from an unselected random bred strain (C) from the same base population.

The study involved 30 litters of line C and 38 litters of line G, from generation 33 of both lines. Two mice of each sex were sampled from each litter, and weighed weekly beginning the day after birth, to 16 weeks. From weaning, at three weeks, they were housed four to a cage, by sex and strain. At 16 weeks, numbers were reduced by random sampling within litters to a total of 16 per sex per strain, representing 30 and 32 litters for C and G respectively, and the number per cage was reduced to two. 'White diet', with a guaranteed analysis of not less than 24% crude protein and 6% fat, and not more than 3.5% crude fibre, was fed *ad libitum* throughout the experiment.

The 64 animals selected at 16 weeks were weighed at 4-week intervals until they died from 'natural' causes. An autopsy was carried out on the majority of the animals, and the incidence and location of tumours and other abnormalities noted.

Mean life span for both lines, by sex, is given in Table 1. On average, animals from line G had a life span only 57% that of those from line C.

Table 1 Mean lifespan (weeks) for two strains of mice: control (C) and rapid 3–6-week body weight gain (G)

Line	Males		Females	
	n	$X \pm$ s.e.	*n*	$X \pm$ s.e.
C	16	112.1 ± 5.4	16	119.5 ± 3.8
G	16	51.1 ± 5.7	16	82.3 ± 3.2

Since all animals of both strains in this study had the same diet, the results are in agreement with the finding[2] that growth rate is more important than dietary composition in influence on lifespan.

There was a significant interaction between line and sex in that females in line G lived about 60% longer than males, while the two sexes in line C did not differ significantly in longevity.

Previous work with these strains had shown that line G mice have significantly higher food intake and body fat percentage than line C[5–8]. Based on data from nutritional manipulation experiments with rats^{1,2}, it seems probable that the premature ageing in line G is associated with obesity.

A variety of tumours, in terms of tissues and sites, was observed at autopsy; a pattern already noted in rats^{2}. The numbers of animals found to have tumours when autopsied was similar in the two sexes, and non-significantly higher in line G (48%) than in line C (39%). Since the life span in line G was considerably shorter than that in line C, it seems that tumours develop earlier in line G, and probably more frequently. A relation between tumour risk and calorie intake in rats is known to exist^{9}.

Mean lifetime body weights for both lines and both sexes are shown in Fig. 1. The number of animals for determination of the means decreased with time, and thus the reliability of the estimates of line mean weights becomes progressively less. However, lifetime growth curves for the later surviving mice were very similar to those shown for all mice, and the difference between the two strains in growth pattern is clear. Selection for rapid 3–6-week gain resulted in a considerably higher mature weight in line G than in line C. Line G mice attained maximum weight at an earlier age than those in line C, and then promptly declined, to a value about 40% below the maximum and near that of the control. In both lines, males attained maximum weights at earlier ages than did females.

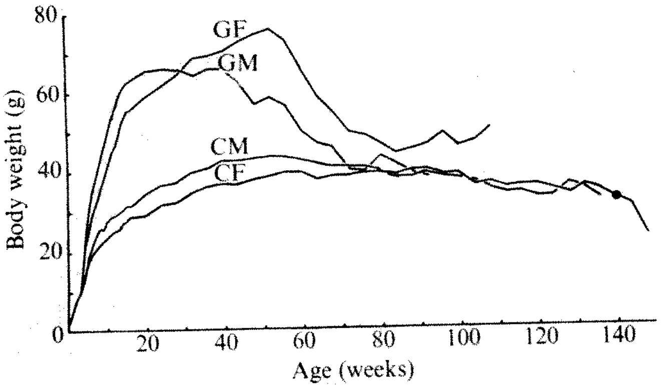

Fig. 1 Mean body weight (g) plotted against age (weeks) for males and females of two lines of mice: control (CM and CF) and rapid growth (GM and GF).

Roberts^{3} studied longevity in mice selected for increased body weight. All animals were mated in that experiment, so the results on longevity cannot be compared with those in this study, at least with regard to females, and possibly also not for males^{10}. Roberts' results are, however, very similar to ours with regard to the earlier attainment of maximum body weight in animals selected for rapid growth, followed by a marked decline in weight beginning shortly after attainment of maximum weight and continuing until death. This decline he attributed to a depletion of fat reserves, also indicated by the appearance of our mice.

Experimental studies of longevity are of necessity costly, and time consuming. Male mice of strain G described here had a mean lifespan, under good husbandry conditions, of just under one year, which may represent the shortest lifespan available in a mammalian species readily available for experimentation. This, coupled with the fact that the strain is known to differ from the the unselected control in food intake, body composition, food conversion and certain other physiological parameters, and that the pattern of tumour incidence at death is apparently quite similar to that in rats with nutritionally induced variation in lifespan, suggests that it may be a particularly useful model for studying causal relationships between food intake, growth, obesity, and ageing.

We thank Oskar Lang, who carried out the autopsies.

Naloxone-induced inhibition of ethanol dependence in mice

It has been suggested that tetrahydroisoquinoline (TIQ) alkaloids formed *in vivo* after ethanol ingestion represent metabolic sequelae linking the types of addiction caused by ethanol and the opiates^{1,2}. The theory derives from the fact that biosynthesis of opiate alkaloids involves TIQ intermediates^{3}, and that TIQ formation from β-arylalkylamines and aldehydes proceeds rapidly at physiological *p*H (ref. 4). There have been strong criticisms of this hypothesis$^{5-7}$, but the demonstration of an effect on opiate activity by certain neuroamine-derived TIQs$^{8-10}$ prompted us to investigate the question further. Specifically, it was interesting to know the effect of naloxone, an agent known to block the development of dependence to opiates^{11}, on the development of dependence on ethanol.

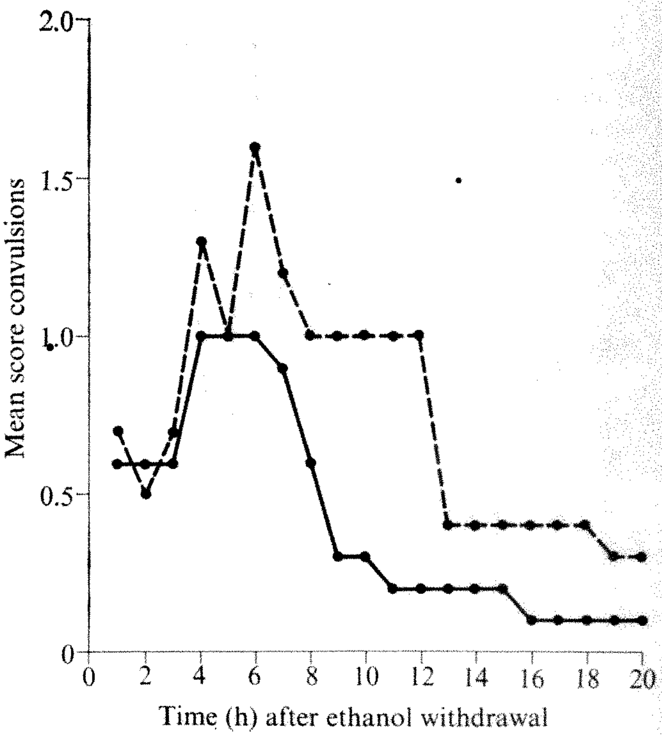

Fig. 1 Effects of chronic naloxone injection of the ethanol-induced withdrawal response in mice (——). Naloxone (2 mg kg^{-1}) was injected intraperitoneally every 6 h for 1 d before exposure to ethanol and every 6 h for 3 d during exposure for a total of 16 injections. Control mice (- - - - - - -) were injected with saline at the same time and with the same volume as the naloxone-treated mice. At least ten mice were used in each group.

Physical dependence on ethanol was induced in male Swiss-Webster mice (18–25g) by the technique of Goldstein and Pal[12]. Groups of 24 mice were housed in airtight chambers and exposed to ethanol vapour carried by a slow stream of air for 3 d. Daily throughout the experimental period, concentrations of ethanol in blood and air were determined[14]. The animals received either naloxone (2 mg kg^{-1} in saline) or equivalent volumes of saline every 6 h for 1 d before exposure to ethanol vapour, and every 6 h for 3 d during exposure. A priming dose of ethanol (1.67 g kg^{-1}, 25% v/v) and pyrazole (68 mg kg^{-1}), a compound known to inhibit ethanol metabolism and thus ensure stable blood ethanol concentrations[13], was injected intraperitoneally on the first day of exposure to ethanol. Drug doses were calculated as the base form rather than the salt. On the second and third days, the mice were removed from the chamber once a day for 45 min for collection of tail blood samples and the single daily injection of pyrazole, and every 6 h for injections of naloxone or saline. Withdrawal was induced on the fourth day by removal of the mice from the ethanol chambers. Withdrawal severity, as measured by convulsions on handling has been described. Pyrazole control experiments, in which pyrazole was injected daily (68 mg kg^{-1}) without ethanol vapour, produced no significant convulsions when the drug was withdrawn on the fourth day.

The 6-h injections of naloxone significantly inhibited ($P < 0.01$) convulsions in response to withdrawal of ethanol. Scores were lower (14 times) at peak differences than those of the paired saline control. The mean convulsion score for saline was 0.76 ± 0.05, whereas that for naloxone was 0.46 ± 0.04 ($P < 0.01$), showing marked inhibition of ethanol dependence in mice (Fig. 1).

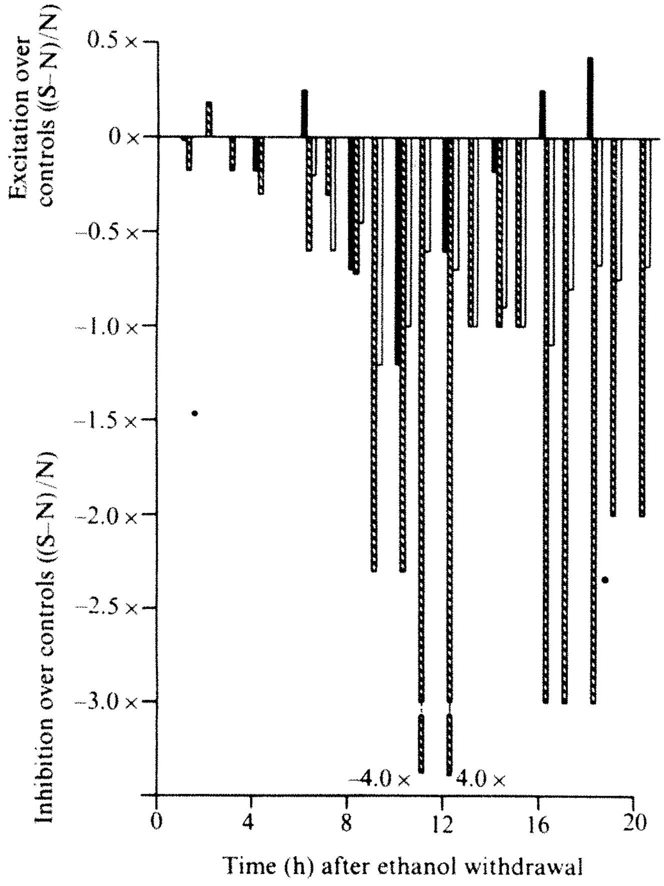

Fig. 2 Effects of naloxone on ethanol withdrawal convulsions from each of three experiments. The fraction ((S – N)/N) represents withdrawal severity and is calculated from

$$\frac{\text{mean saline convulsions} - \text{mean naloxone convulsions}}{\text{mean naloxone convulsions}}$$

for each of the 20 h listed (see text). Twenty-four mice were used for each experiment. Open columns, experiment 1; hatched columns, experiment 2; filled columns, experiment 3.

To illustrate this further, a composite of three experiments with a total of 72 mice is represented as a histogram in Fig. 2. The experimental protocol was the same as that described above. Naloxone (2 mg kg^{-1}), administered in four divided doses, reduced the withdrawal convulsions consistently and reproducibly in triplicate experiments. We calculated a ratio representing withdrawal severity (WS) according to the following formula

$$\text{WS} = \frac{\text{saline withdrawal score} - \text{naloxone withdrawal score}}{\text{naloxone withdrawal score}}$$

$$\left[\frac{(\text{S}-\text{N})}{\text{N}}\right]$$

When $\text{WS} > 0$, the withdrawal convulsions have been inhibited; when $\text{WS} < 0$, the convulsions have been exacerbated. Fig. 2 shows the percentage inhibition (or excitation) of WS by naloxone during withdrawal from ethanol.

To analyse ethanol in the blood and brain of mice undergoing withdrawal from ethanol vapour, two groups were injected with either saline (equivalent volume as naloxone) or naloxone (2 mg kg^{-1}) every 6 h for 4 d, three of which were during exposure to ethanol. These mice also received daily injections (68 mg kg^{-1}) of pyrazole during exposure, as before. Blood and brain samples were taken from these groups 5, 10, and 15 h after withdrawal. Mice were killed and blood and brain samples from each were analysed for ethanol by gas chromatography[14]. At least five mice were used for each determination.

Ten hours after withdrawal (the time of peak seizure scores) the concentrations of ethanol in the blood or brain after administration of saline were 41.5 ±3 mg dl^{-1} and 35.7 ±4 mg dl^{-1}, respectively; these values do not differ significantly from those obtained after administration of naloxone, which were 47.5 ±2 mg dl^{-1} and 43.7 ±2 mg dl^{-1}, respectively. Similarly, naloxone did not affect the concentrations of ethanol at 5 h after withdrawal. Thus, the effect of naloxone on convulsions induced by withdrawal of ethanol do not seem to be related to an alteration of ethanol metabolism.

We next analysed brain calcium in mice given naloxone or saline and then exposed to ethanol vapour using the modified wet ash procedure of Cardenas and Ross[21].

Mice were divided into two groups of twelve. Group *A* received an injection of naloxone (2 mg kg^{-1}) every 6 h, and group *B* received an equivalent volume of saline. They were treated 24 h before exposure to ethanol. The injection schedule continued daily for 3 d before withdrawal convulsions were recorded. Pyrazole (68 mg kg^{-1}) was injected as before.

Table 1 shows that chronic exposure to ethanol produces a significant decrease ($P < 0.01$) in brain calcium, to 70% of control in the first 24 h. On the second and third day of ethanol exposure, the effect was similarly significant ($P < 0.05$), though less effective, depleting calcium to 78 and 84% of control values, respectively. Naloxone, which by itself has no significant effect on brain calcium levels, prevented the ethanol-induced depletion of brain calcium ($P < 0.05$). These results suggest that the effect of naloxone on ethanol-induced withdrawal convulsions is mediated, at least in part, through an action on calcium metabolism in the central nervous system.

The finding[7] that naloxone, an agent known to precipitate jumping in morphine-tolerant mice[15], does not have this effect when administered acutely to ethanol-tolerant mice, cast doubt on the alkaloid biogenesis theory linking opiate and ethanol actions. Nonetheless, several lines of research have produced evidence that argues for such a relationship. Thus, cross-tolerance betweeen morphine and ethanol[16], increased tolerance

Table 1 Naloxone blockade of chronic ethanol-induced depletion of brain calcium in mice

Treatment	Brain calcium during chronic ethanol exposure* (mg g^{-1} (mean±s.e.m.) wet weight)		
	Day 1	Day 2	Day 3
Saline (equiv. volume to naloxone+ethanol vapour)	36.0±4.8†	39.9±0.3†	43.2±1.6†
Naloxone+ethanol vapour naloxone was administered at 2 mg kg^{-1} every 6 h (24 h before and every day during ethanol vapour exposure)	51.0±2.6‡	45.8±3.8‡	45.1±4.8‡

Ten mice were used for each determination.
Calcium value for control brain = 51.0±6.3 and for naloxone (2 mg kg^{-1}) = 52.2±2.0.
* Mice were killed 24 h apart (day 1 = 24 h exposure, day 2 = 48 h and day 3 = 72 h).
† Values significantly different from controls ($P <$ at least 0.05).
‡ Values not significantly different from controls.

to morphine in ethanol-habituated animals and man[17], inhibition of ethanol withdrawal convulsions by morphine[18], and attenuation of ethanol-induced narcosis by naloxone[19] have all been demonstrated. Furthermore, the TIQ alkaloid, 3-carboxy-salsolinol (the L-dopa-acetaldehyde adduct) potentiates ethanol-induced narcosis[20] and morphine analgesia[10] in mice, and salsolinol (the dopamine acetaldehyde adduct) interacts with the opiate receptor of the guinea pig ileum[9]. Our demonstration of inhibition of ethanol-induced withdrawal convulsions and blockade of ethanol-induced calcium depletion by naloxone provides further evidence for a functional relationship between opiates and ethanol.

We emphasise, however, that the results of these experiments and the others mentioned here, showing antagonism by naloxone of non-opiate drugs, must be viewed with caution. It is possible that naloxone, although considered to be a specific opiate receptor antagonist[11], has other actions so far unappreciated. The results would then simply reflect the action of naloxone at this alternate site(s) of action.

Nonetheless, the present state of knowledge supports our interpretation that ethanol and the opiates share some common biochemical mechanisms, and further research to delineate these mechanisms is warranted.

This research was supported by grants from the Pharmaceutical Manufacturers Association and the Air Force Office of Scientific Research. We thank Ben Wiggins, Raul Marin, Charles O. Shore, Steve Elston, Michael E. Wallace and Joseph Eubanks for technical assistance. We also thank Dr Boris Tabakoff for the formula of the CSF we used. K. Frog retinal ganglion cells show species differences in their optimal stimulus sizes

THE purpose of this study was to compare the optimum stimulus sizes of class 2 ganglion cells in *Rana pipiens* with those of *R. catesbeiana*. Several neurophysiological studies have suggested that activity in class 2 ganglion cells in the frog retina (convexity sensitive[1–3]) serves as a trigger for prey catching[1,4]. Field studies of the stomach contents of various species of frogs show that the prey selected by the bullfrog, *R. catesbeiana*, differs from that of the leopard frog, *R. pipiens*, in size. Bullfrog stomachs have contained (in addition to insects) crayfish, frogs, mice, and birds[5,6]. Leopard frogs generally prey on various insects, spiders, and terrestrial snails[7,8]. This study was undertaken to explore a possible difference in the electrophysiological optimal stimulus size for class 2 retinal ganglion cells of leopard frogs and bullfrogs which might be related to differences in prey size preference. Our data suggest that bullfrog ganglion cells have average optimal stimulus sizes significantly larger than those of leopard frogs.

The experiments described were conducted on adult frogs of northern North American origin. Leopard frogs ranged in body weight from 14.0 to 46.5 g, while bullfrogs weighed from 222 to 440 g. All frogs were acclimatised in the laboratory at 20–22 °C. for at least two weeks before use and were fed every two days. The animals were anaesthetised for the duration of the surgery with MS:222. The cranium was opened to expose the tectum. Paralysis was achieved with injection of neuromuscular blocking agents and xylocaine was infused into the incision site. MS:222 was then discontinued for the recording period. Frogs were dark-adapted for 1 h before recording began. Conventional electrophysiological techniques were used to record from optic nerve terminals in the tectum[9]. Platinum-plated, alloy-filled glass micropipettes of 3–5-μm tip diameter[10] were employed for the recordings. Electrical data were recorded on an A.M. tape recorder for later analysis. Spike trains from single neurons were resolved with a pulse height discriminator and the action potentials counted using a PDP-11 data acquisition computer system.

Visual stimuli consisted of black, round spots projected on to the back of a translucent tangent screen situated 24 cm from the frog's eye. Background illumination of the screen measured at this distance with a Weston Model 614 foot-candle meter was 3–4 ft cd. The spots were produced photographically on a transparent film strip and ranged from 2.3° to 28° in diameter (i.e. the angle which the diameter of the spot subtended at the eye) in seven discrete sizes. Each size was presented twice, with 35 s allowed between presentations. A motor-drive moved the filmstrip through a projector so that the spots travelled horizontally across the screen at a constant, 7° s^{-1} angular velocity, through the centre of the excitatory receptive field (ERF) of each cell.

The topography of the retino-tectal projection onto the optic tectum was found to be similar in the bullfrog and leopard frog, and the same as described for other Ranid species[11,12]. In both species, units were recorded from the mid-lateral region of the tectum which receives input from the central visual field to avoid disparities which might be caused by sampling from different fields. Class 2 cells were identified according to the following criteria: the cell responded best to small moving objects: it showed a sustained, movement-gated response to a stationary stimulus positioned in the ERF[8]; the sustained response had to be 'erasable', i.e. transient darkness would permanently extinguish the on-going response[8,9]; and the cell showed a brief response to the general 'OFF' of light, but a weak, habituating response to the 'ON'. After the cell was identified as a class 2 type, the approximate extent of the ERF was mapped with a 2° spot. Then the response of the cell to each of the seven different stimulus sizes was determined. The computer was used to count individual spikes produced by the cell and also to measure the between-spike intervals. Spikes occurring after intervals longer than 50 ms were discarded and the response was then scored as the number of action potentials greater than or equal to 20 Hz. This frequency was chosen in order to eliminate background and low level activity. The cell's response was plotted against the logarithm of the area of each stimulus spot (Fig. 1). In order to determine the optimal stimulus size from the experimental data, we fitted a quadratic function to each cell's response profile (Fig. 1), using a computerised, stepwise, polynomial regression procedure. The goodness of the fit was tested for each case by an F test. All values of F so obtained were greater than 5.7 (d.f. 2/11) which is significant at better than the 0.025 level (most values exceeded the 0.01 level). By differentiating the quadratic equation, we calculated the maximum of the curve which lies over the stimulus area that elicited the maximum response. From this area, we calculated the diameter of the optimum stimulus spot size in degrees for each cell, individually.

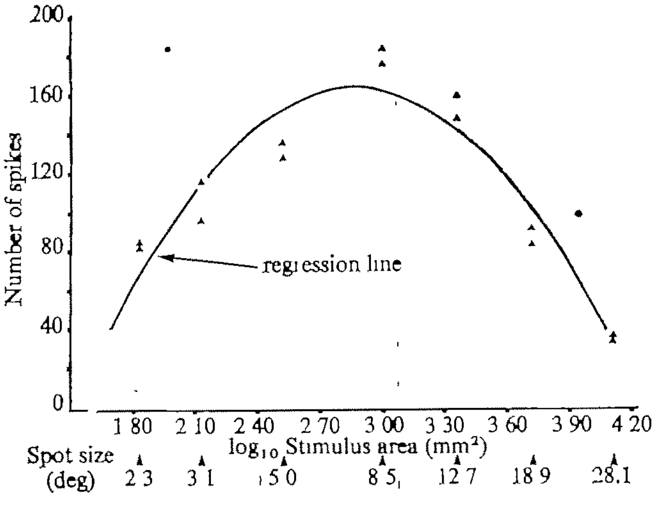

Fig. 1 Data obtained from one bullfrog class 2 ganglion cell. This figure demonstrates the technique used to determine the optimal stimulus size for the neuron. ▲, The response of the cell to the various spot sizes used. Each spot size was tested twice. The curve is the quadratic function fitted by a computerised polynomial regression procedure ($F = 46.4$) For a quadratic equation of the form $y = a+bx+cx^2$, the point of zero slope, $dy/dx = 0$, is given by $b+2cx = 0$. This yields $x = -b/2c$ which predicts the maximum of the curve. In the case illustrated above, the maximum lies over the log stimulus area of 2.88, corresponding to a spot size of 7.4° or a stimulus area of 758.6 mm^2 The equation of the regression line shown is

The results from 25 cells from 8 leopard frogs and 31 cells from 12 bullfrogs show that the optimum stimulus sizes of leopard frog class 2 cells average 5.22° (s.e. 0.3°), while the average for the bullfrogs is 7.77° (s.e. 0.21°). These values indicate that the bullfrog optimum stimulus requires a 50% larger diameter, or a 100% larger area than the optimum for leopard frogs. The null hypothesis that these two samples come from the same population may be rejected at $P < 0.001$ (Mann-Whitney U test). Our size optimum found in *R. pipiens* is comparable to the 3°–5° optimum found in *R. esculenta* class 2 cells by Butenandt and Grüsser[13]. This European frog is similar in size to the leopard frog. More interesting, perhaps, than the mean of the optimal stimulus sizes is the distribution of these sizes (Fig. 2). Although there is overlap of size optima between both species, bullfrogs exhibit many cells with larger optima. Of our sample, 74% of bullfrog cells responded best to objects larger than 7°, whereas 84% of leopard frog cells responded best to objects smaller than this size.

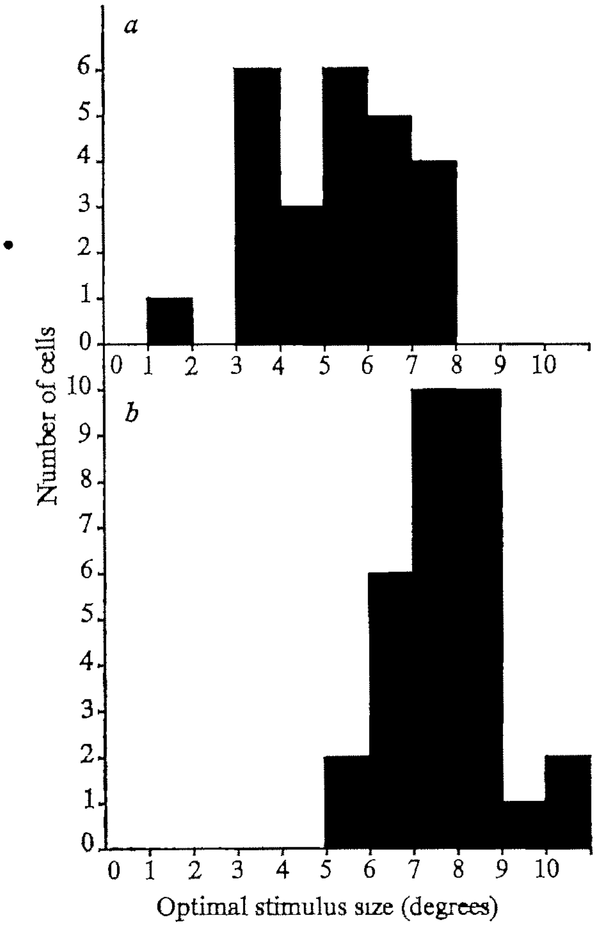

Fig. 2 Distribution of optimal stimulus sizes for 25 leopard frog (*a*) and 31 bullfrog (*b*) class 2 retinal ganglion cells determined by single unit recording of the responses of these cells to spots of different sizes moved across their receptive fields at a velocity of 7°/s. The average optimum stimulus size for the bullfrog cells was 7.77°, compared to 5.22° for leopard frog cells. Of bullfrog cells, 74% had size optima exceeding 7°, while 84% of leopard frog cells had a lower size optima.

Two conceivable difficulties with the interpretation of our results deserve mention First, we may not have sampled cells from comparable parts of the retina in both species of frog. Across many species of vertebrates, receptive field sizes of

Circle No. 03 on Reader Enquiry Form.

The Science Dictionaries

Three useful and up-to-date works of reference intended not only for students, teachers and researchers but also for science journalists and the general reader.
Each book is designed for easy use – entries are arranged alphabetically and defined under the most common form of term, with synonyms in brackets. S.I. units are used throughout and all entries are thoroughly cross-referenced.

A Dictionary of Life Sciences
E. A. Martin

The recent trend to treat the biological/life sciences as a whole rather than divided into separate units is reflected in this concise dictionary which brings together in one volume all the main branches of zoology and botany. Selected terms in related fields of biochemistry, endocrinology, animal behaviour and palaeontology are also included. All major plant and animal classes are fully described as well as the more important orders, and common names of animals and plants are cross-referenced to their appropriate taxonomic groups.

1976 £5.95 392pp

A Dictionary of Earth Sciences
Stella E. Stiegeler

The subjects covered here include geophysics, structural geology, geomorphology, oceanography, stratigraphy, palaeontology, sedimentology, climatology, meteorology, soli science, cartography, mineralogy, petrology and surveying. The terms defined reflect the recent modification of traditional concepts and the resulting development of terminology in the earth sciences. In soil science, for example, a new system of classification is now in in use, with a completely new terminology for the soil orders.

1976 £5.95 320pp

A Dictionary of Physical Sciences
John Daintith

This book covers the main branches of physics, chemistry and astromony – from Abbe condenser to zoom lens and zwitterion. A selection of relevant terms from the related fields of electronics, computer science and mathematics is included. Full accounts are given of the properties and uses of the chemical elements and many of their compounds. All the chemical terminology used is that recommended by the International Union of Pure and Applied Chemistry.

Proceedings of the 12th Annual Symposium of the Eugenics Society

Equalities and Inequalities in Health

Edited by C. O. Carter and John Peel

January/February 1977, x + 170pp., £4.80/$10.50 0.12.161850.1

Leading experts from a number of fields including medicine, biology, sociology and administration seek in their papers to outline and examine the ways in which genetic, environmental and societal factors affect health. The survey is not limited to the United Kingdom, but discusses the growth of health services in the developing countries. It also draws comparisons between Britain and other European countries.

Studies in Cognition and Perception

Aspects of Tone Sensation

Reinier Plomp

January/February 1977, x + 168pp., £6.50/$14.75 0.12.558350.8

Great progress has been made in the field of tone perception over the last two decades. This book reflects these advances and presents an up-to-date review of the psychophysical data and concepts in the field of steady-state tone sensation. Information about the interaction of tones and about the three main attributes of complex sounds — loudness, timbre and pitch — are among the exciting discoveries that have resulted from new experimental evidence and which are featured in this work.

Theoretical Chemistry: a series of monographs No. 6

Electron Correlation in Small Molecules

A. C. Hurley

January/February 1977., viii + 276pp., £10.50/$23.00 0.12.362450.9

A series of pair theories of progressively increasing sophistication relating the important correlations in larger molecules to those in two-electron systems has recently developed. This monograph gives a systematic account of these pair theories and other approaches to the correlation problem, starting from molecular Hawtree-Fock theory and the correlation theory for two-electron systems.

The Analysis of Organic Materials An International Series of Monographs No. 9

Aldehydes — Photometric Analysis Volume 4

January/February 1977, x + 288pp., £12.00/$26.25 0.12.620504.3

Here is the fourth in this comprehensive series on the photometric analysis of aldehydes. It discusses the photometric analysis of precursors through their derived aldehydes and also the formation of aldehydes through a variety of reactions. In the future, the latter could be of increased importance in the development of methods of analysis utilizing photometry, gas chromatography, high performance liquid chromatography and mass spectrometry.

Society for Applied Bacteriology Symposium Series No. 5

Inhibition and Inactivation of Vegetative Microbes

Edited by F. A. Skinner and W. B. Hugo

January/February 1977, xiv + 378pp., £12.00/$26.25 0.12.648065.6

These papers review some of the fundamental principles of microbial inactivation and show how they can be applied in practice. Methods which receive detailed appraisal include heat, cold, chemical (including gaseous) treatment, irradiation, application of high pressures and the alteration of water activity as encountered in preservation procedures involving brines and syrups. Problems in specialist areas where microbial growth may be inimical are also discussed.

The Biology of The Sticklebacks

R. J. Wootton

January/February 1977, x + 388pp., £13.50/$29.50 0.12.763650.1

Studies on the stickleback have made important contributions to the fields of animal behaviour, reproductive physiology, evolutionary biology, parasitology and ecology. Accounts of these studies are scattered throughout the zoological literature. This book aims to present a coherent and thorough account of the biology of the three-spined stickleback; one which will enable particular studies of the species to be interpreted in the context of the known biology of the fish.

The Development of Cognitive Processes

edited by Vernon Hamilton and Magdalene D. Vernon

January/February 1977., x + 772pp., £21.00/$46.00 0.12.321750.4

This book is intended for all psychologists interested in the various aspects of cognitive development in children, especially as elucidated through the application of the information processing concepts which have recently been extensively employed in the investigation of adult cognition. Readers will gain an insight into the prospects for future developments in the study of cognitive processes in children.

Cell Biology International Reports has been established by the International Federation for Cell Biology to improve communication between scientists working in cell biology and related fields. The journal's flexible approach will allow for varied presentation of material. Particular importance will be given to the rapidity of publication together with brevity and clarity of expression. Black and white photographs, electron micrographs and line drawings will be used to illustrate the reports.

The Journal will publish papers describing original work on any topic in cell biology and related fields as well as papers which develop important new conclusions from published information. Short reports on methods, if these contain new principles or represent technical advances of importance and short accounts of meetings of general interest which would not otherwise be recorded will also be published.

Papers to appear in the first issue will include;

L. M. Franks: The Scientific Paper — 1977. A note from the Editor
H. B. Fell: The evolution of the International Federation for Cell Biology
S. M. Whelly and R. Baserga: Relationship between cell proliferation, chromatin template activity and accumulation of nuclear proteins
D. Nishioka and D. Mazia: The phosphorylation of thymidine and the synthesis of histones in ammonia — treated eggs and egg fragments of the sea urchin
B. C. Wu, M. S. Rao, K. K. Gupta, L. I. Rothblum, P. C. Mamrack and H. Busch: Evidence for coupled synthesis of mRNA for ribosomal proteins and rRNA

A Textbook of Human Anatomy

EDITED BY W. J. HAMILTON

The new edition of this well-known and widely used textbook has been completely revised in order to bring it up-to-date with recent advances in fields of medicine such as immunology.

The number of illustrations has been considerably increased and includes some excellent four colour plates.

The format of the book has been enlarged and the layout clarified.

Publication date October 1976 Price £14.50 768 pages SBN: 333 181 158

Human Embryology

HAMILTON, BOYD AND MOSSMAN

Fourth Edition revised by
W. J. Hamilton and H. W. Mossman

This classic text has been the standard authority since it was first published in 1945.

In its revised form the fourth edition contains several new sections including a chapter on the development, structure and functional activities of the placenta and a large number of new micrographs.

Such a book will be an essential reference work for medical students, research workers, clinicians and surgeons.

'This finely produced and scholarly book will remain the definitive English text for many years'
British Medical Journal

£16.00 SBN: 333 19153 6

The Human Placenta

BOYD AND HAMILTON

'The production of this book is a publishing event of importance. Two of the most distinguished anatomists with a special interest in the human placenta have combined, as often they have before, to write and of course illustrate a classic . . . Of course the book is expensive. Such a lavish feast of riches, the product of a lifetime's work and thought allied with the best of the publisher's art, could scarcely be otherwise. No department of anatomy, of obstetrics and gynaecology, of reproductive physiology, or of endocrinology, can consider its library complete without possessing a copy of this elegant informative volume'
Philip Rhodes *British Medical Journal*

£25.00 SBN: 333 19186 2

Surface & Radiological Anatomy

For students and General Practitioners

Fifth Edition

HAMILTON, SIMON AND HAMILTON

Increasing emphasis is now being given to the study of anatomical structures which are accessible to examination in the living subject and this beautifully produced book answers a need for an authoritative text on the subject.

In this fifth edition several changes have been made, many of the original micrographs have been replaced.

'The editorial trinity have established a wonderful text; the association of an anatomist, a radiologist and a surgeon seems to be ideal'
The British Journal of Surgery

1975 £9.50 SBN 333 191544

3.8.76

ganglion cells increase from retinal centre to periphery[14]. Optimum stimulus size is roughly proportional to receptive field size in the frog retina[13]. If the optic axis of the bullfrog is different from that of the leopard frog, we could have sampled cells from non-analogous retinal regions, thereby introducing a possible discrepancy into our measurements. However, the similarity of the retinotectal projection between the two species which we have observed, and the similarity of their visual fields of view as revealed by perimetry[15], lead us to doubt that a significant difference exists in the optic axis. Secondly, there is the possibility that the two species of frogs studied have had different refractive errors, resulting in varying degrees of retinal defocusing when both animals viewed the projection screen at the same 24 cm distance. We performed reflection retinoscopy on paralysed frogs and detected consistent, but small differences in the refractive errors of the two species. Leopard frogs were slightly myopic and bullfrogs were slightly hypermetropic. The errors measured however were less than 1.5 diopters and therefore were not considered to be large enough to defocus seriously the retinal image or to cause substantial disparities in retinal image size.

Technically, we note that the retinal image size of a given object at a constant viewing distance will be larger in the bullfrog eye than in the leopard frog eye, assuming that the refractive indices of cornea, lens, and vitreous are identical in both species. The linear extent of the image on the bullfrog retina will exceed that of the leopard frog in the same proportion as the ratio of the posterior focal lengths of their eyes. This disparity in size would lead one to predict that bullfrog retinal ganglion cells, if there were no differences in retinal circuitry, would have smaller optimal stimulus sizes than those of leopard frogs. Our observation, however, that in fact the reverse is the case, supports the existence of such a difference.

Behavioural experiments have indicated that, in addition to size cues, other factors are important for initiating prey catching in frogs. Olfactory input suggestive of prey can influence toads to choose larger than usual prey objects[16]. Motivation to feed may affect size preference[17] as does satiety level[18]. The contrast of the object with the background as well as the season is significant[19]. 'Predator-like' visual stimuli excite neurons in the thalamus and pretectum which in turn inhibit tectal neurons, thereby blocking prey catching[20,21]. Single unit recording of retinal ganglion cells cannot elucidate all the complexities of prey catching that behavioural experiments have revealed (see, for example, Ingle[22]). Prey catching does not follow activity in class 2 fibres in a one to one fashion. It is true, however, for the frog retina, that highly processed information about a visual stimulus is presented to the brain. We hypothesise that encoded in class 2 responses are size cues which may be one of several important triggers for prey catching. The differences in the size cues emitted by the retinae of frogs of different species may be the first step in producing a difference in prey size preference.

We thank Professor J. C. Ogilvie and Mr. John Kornatowski for their assistance. This work was supported by National Research Council of Canada Grant No. A5455 and an NRC Post-graduate Scholarship to R.D.G.

Normal postimplantation development of mouse parthenogenetic embryos to the forelimb bud stage

PRE- AND POSTIMPLANTATION development of parthenogenetic embryos is of interest in analyses of the role of the male genome in early mammalian development, differentiation, and in haploid and diploid gene expression in embryogenesis. Diploid and haploid mouse parthenogenones evidently possess the capacity to form teratomas and give rise to differentiated tissues[1,2] although normal organogenesis has not been observed to progress beyond the early somite stage *in utero*[3]. Birth of live parthenogenetic rabbits has been reported[4–8], and Beatty[9] has estimated that 1 in 200 embryos induced under similar conditions can be expected to reach term. There is, however, some doubt about the validity of this early work since subsequent attempts to repeat it have failed to obtain development beyond the blastocyst stage[10,11]. Mouse parthenogenones develop to the egg cylinder stage but only one 8-somite embryo has so far been obtained[3,12]. We have examined the postimplantation development of diploid mouse parthenogenones and report that a high proportion progressed to somite embryos when blastocysts were transferred to pseudopregnant recipients. Recipients were ovariectomised following embryo transfer and their pregnant state maintained with exogenous hormones. Two apparently normal forelimb-bud stage embryos with a beating heart and yolk sac circulation were obtained. Other embryos isolated from the same recipient showed disorganised development, and a twin conceptus was obtained from a further recipient.

Cumulus masses from the oviducts of 8–12-week old (C57BL × CBA)F_1 hybrid mice were released at about 18 h after the HCG injection for superovulation into modified Krebs-Ringer bicarbonate embryo culture medium[13] containing 4 mg ml^{-1} bovine serum albumin but lacking calcium and magnesium salts (M.A.H.S. and M.H.K., in preparation). After 5–6 h adherent cumulus cells were removed with hyaluronidase, and the eggs examined to determine the activation frequency and types of parthenogenones induced (Table 1). Activated eggs were separated into their different types, transferred to normal embryo culture medium[13] and retained in culture for a further 90 h. By this time 91 out of 178 of the presumptive diploid[14,15] 2-pronuclear embryos had developed to the expanded blastocyst stage. Blastocysts were transferred to a single uterine horn of d 3 pseudopregnant recipients previously mated to proven sterile vasectomised males (day of finding vaginal plug=d 1 of pseudopregnancy). The recipients were bilaterally ovariectomised immediately after transfer of blastocysts and thereafter maintained on exogenous steroid hormones. After an initial hormone-free period of 2 d, recipients were maintained for 4 d on 1 mg progesterone daily per animal, during which time blastocysts presumably enter into quiescence.

Table 1 Types of parthogenones induced in HCG+18 h group in medium lacking Ca^{2+} and Mg^{2+}

Total no. of eggs examined	Activated eggs (%) 1 pronucleus +2PB*	2 pronuclei without 2PB	1 pronucleus without 2PB	Immediate cleavage	Overall activation frequency (%)
731	58 (11.8)	243 (49.3)	27 (5.5)	165 (33.5)	67.4

*Second polar body.

Implantation was initiated by injecting 20 ng oestradiol along with progesterone for 3 d, and thereafter pregnancy maintained with 8 ng oestradiol and 1.6 mg progesterone daily per female.

Implantation began about 24 h after the initial injection of oestradiol, which is equivalent to about d 5 of pregnancy, and recipients were killed at intervals between the 6th and 11th day of "pregnancy". About 80% of the transferred blastocysts implanted (Table 2), and all implantation sites up to d 9 were immediately fixed in Bouins solution and examined histologically. After d 8 of "pregnancy", embryos were dissected from the uterus and examined under a dissecting microscope. The two most advanced embryos obtained were at the forelimb-bud stage on the 11th d of "pregnancy", both had about 25 somites and were apparently healthy with beating hearts and a good yolk sac circulation at the time of isolation from the uterus. These embryos were later fixed for histology (Fig. 1*a* and *b*).

Table 2 Implantation rate and development of diploid (2 pronuclear) parthogenetic blastocysts in ovariectomised recipients given exogenous steroids

Day of "pregnancy" at autopsy	Total no. of recipients	Total blastocysts transferred	Total implantations	Total embryos	Approximate stage of development
6	1	3	3	1	Early egg-cylinder
7	2	14	10	3	
8	1	13	10	4	Advanced egg-cylinder
10	3	15	12	2	4-8 somite embryos
11	2	9	8	5	25 somite embryos (× 2) Disorganised embryos (× 2) Twin conceptus, one with 10 somites

Several factors may account for the improved results reported here compared with the only other comprehensive study on postimplantation mouse parthenogenetic development[3,12]. The mode of activation of eggs in Ca^{2+}/Mg^{2+}-free medium has not been used before and may be less traumatic than electrical stimulation of eggs *in vivo*[3] or hyaluronidase activation *in vitro*[16,17]. The choice of the F_1 hybrid where one-cell eggs develop to the blastocyst stage *in vitro*[15,18] is unusual since embryos from other strains do not normally progress beyond the 2-cell stage *in vitro*. The use of ovariectomised recipients may permit a better synchrony between blastocysts and the uterus before implantation commences. Blastocysts in this instance were allowed to enter into quiescence before implantation was stimulated. An increase in cell number occurs as embryos enter into quiescence[18] and would approximately double the number of cells in blastocysts before implantation.

Parthenogenetic blastocysts are similar to normal fertilised blastocysts when examined ultrastructurally[19]. Their cells can also differentiate into a variety of cell types in ectopic sites[1,2]. In the present study 35% of implanted embryos developed into normal egg cylinders, and 25% developed to somite-stage embryos.

The present study indicates that non-fertilised parthenogenetic eggs are capable of apparently normal development to a very advanced state in the absence of any genetic or extragenetic contribution from sperm. Since a greater number of embryos develop normally after fertilisation, the

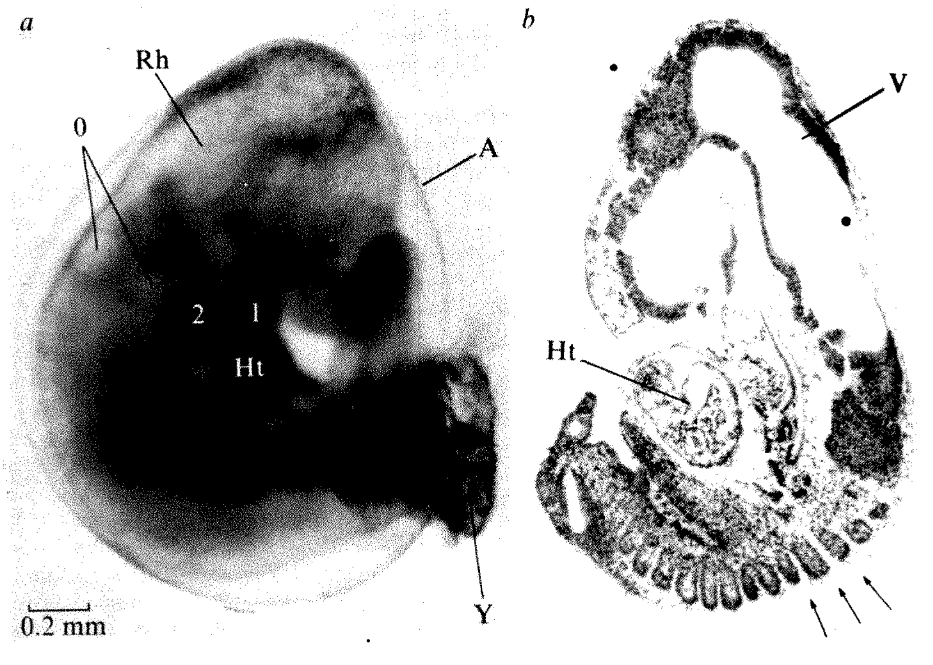

Fig. 1 *a*, Parthenogenetic mouse embryo with about 25 somites photographed within its amnion, unfixed preparation. *b*, Near sagittal section of embryo in *a* showing large number of well formed somites (arrowed). Embryo fixed in Bouins about 4 h after isolation from the uterus. Scale bar represents 0.2 mm; 1 and 2, first and second branchial bars; O, otic vesicle; Ht, heart; Rh, rhombencephalon with 4th ventricle; A, amnion; Y, yolk sac; V, 4th ventricle.

role of sperm is probably to prevent imbalance in the genetic constitution of the zygote. In the present study 60–70% of the embryos which successfully implanted died shortly thereafter, leaving about 25% to develop normally to somite embryos. In some embryos anomalous development may manifest itself in disorganisation of the embryo such that individual cells remain viable but are unable to form into tissues and organs. Survival of parthenogenones to term will depend on the extent of genetic imbalance in individual embryos which may affect development during critical stages of organogenesis.

Parthenogenetic embryos will be valuable to determine the developmental potential of genetically dissimilar embryos. The role of sperm in the activation of unfertilised eggs can be studied by morphological, genetical and biochemical comparison between fertilised and different types of parthenogenetic embryos. It may be possible to establish haploid and diploid cell lines from unfertilised parthenogenones. This would facilitate biochemical studies on cell surface constituents and their role in histotypic contact and cellular interactions. The disorganisation of some postimplantation parthenogenones probably reflects abnormalities in their cell surface properties which may be analysed by comparisons with the cells of normal embryos.

We thank Mrs Andrea Burling for technical assistance and Mr D. Thurlbourn for caring for the mice. This work was supported by a grant from the Ford Foundation.

Antigenic deletion and malignant enhancement induced in lymphoma cells by passage through X-irradiated hosts

WE report here a new system by which lymphoma cells are induced to delete strong, virus-associated membrane antigens and, as a result, considerably increase their capacity for transplantation and metastasis. This system of inducing antigenic changes in tumour cells is interesting because it involves X-irradiation of the hosts, which is used widely in the treatment of human cancer.

We used lymphoma cells which originated in W/Fu rats injected at birth with Gross leukaemia virus (GLV)[1]. The cells were obtained either fresh from rat thymomas or from our established LT_1 lymphoma tissue culture line that permanently replicates GLV[2]. As a corollary of reproducing the virus, both kinds of lymphoma cells express strong murine leukaemia virus (MuLV) surface antigens (Fig. 2) and are consistently rejected when transplanted into normal, adult, syngeneic W/Fu rats. In rats given 300–350 R total body X irradiation, however, lymphoma cells transplanted within 24 h subcutaneously or intraperitoneally (Table 1) grew progressively at the site of the graft, spread to distant sites occasionally and eventually caused the death of the hosts. Lymphoma cells from such tumours growing in X-irradiated rats were then transplanted into normal, adult, syngeneic recipients, and in contrast to lymphoma cells of thymomas and of tissue cultures (controls, Table 1) were not rejected but grew into large tumours that metastasised widely (Fig. 1) and killed the recipients. Thereafter, such lymphoma cells became serially transplantable in all syngeneic, normal, adult rats, consistently resulting in voluminous tumours, metastases and death.

As described before[1-2], thymoma cells and LT_1 tissue culture cells show GLV C-type particles at the plasma membrane and exhibit positive membrane (MF) and cytoplasmic (CF) immunofluorescence when stained with anti-MuLV serum in indirect immunofluorescence. The membrane fluorescence is ring-like, around the entire cellular circumference and is apparent on almost all cells (Fig. 2*b*), usually brighter on the cells from the culture than on those from thymomas. Lymphoma cells from tumours growing in the X-irradiated rats, however, exhibited different patterns of fluorescence. Only 10–20% of cells showed the

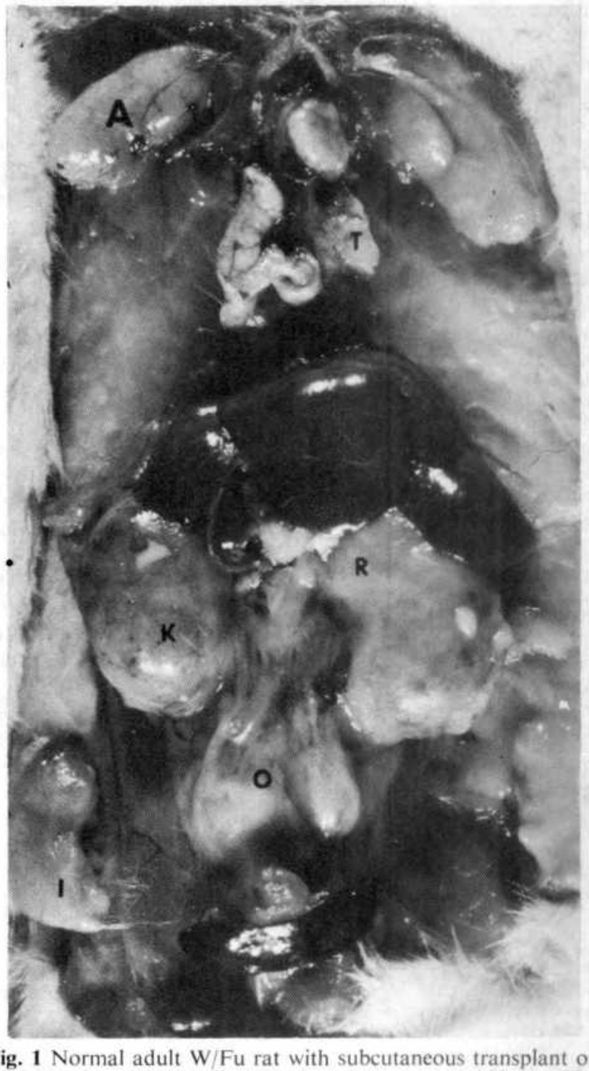

Fig. 1 Normal adult W/Fu rat with subcutaneous transplant of MuLV− lymphoma cells. Massive metastases to kidneys (K), axillary (A), parathymic (T), pararenal (R), para-aortic (O) and inguinal (I) lymph nodes.

ring-like membrane fluorescence, while about 60% displayed capping of fluorescence (Fig. 2*a*) and 20% of the cells had become entirely negative. Tumours examined at longer intervals after transplantation in X-irradiated rats showed a progressive increase in the number of capped and negative cells with a proportionate decrease in the number of cells with positive ring-like fluorescence. Lymphoma cells of recipients that died less than 50 d after transplantation did not show loss of antigenicity as expressed by conversion from MuLV+ to MuLV− in the membrane immunofluorescence assay. Table 2 indicates that a minimum time interval was essential for the antigenic conversion to occur. As the tumours became serially transplantable to new generations of normal adult rats all lymphoma cells became permanently negative in both membrane and cytoplasmic fluorescence (Table 1).

Examined under the electron microscope, the transplantable lymphoma cells appeared devoid of both mature and immature virus particles. To investigate the apparent loss of MuLV antigens further, cytotoxicity assays were carried out using serum of rats that had rejected MuLV-positive lymphoma cells against MuLV-negative lymphoma cells as target cells and MuLV-positive lymphoma cells as controls. The results, expressed as percentages of killed cells, again confirmed the lack of MuLV antigenic expression on the transplantable lymphoma cells. As reported when antigenic conversion was induced by other means[3-5], in our experiments the loss of surface MuLV antigens was consistently accompanied by increased malignancy of lymphoma cells expressed by serial transplantability and capacity for widespread metastases (Fig. 1).

The titres of serum anti-MuLV antibodies were determined in all recipient rats by cytoplasmic indirect immunofluorescence using standard LT_1 cells as previously described[3]. The results (Table 1) unexpectedly showed higher anti-MuLV antibody titres (up to 1 : 4,096) in the normal recipients grafted with MuLV− cells that grew into progressive tumours than in those grafted with MuLV+ cells that were rejected. This might be explained by assuming that a small amount of MuLV+ cells, insufficient to induce tumour rejection but able to elicit antibody formation, was still present in the long-lasting, voluminous MuLV− tumours.

In our experiments, lymphoma cells acquired the capacity for transplantation and metastasis, consequent on the loss of their membrane viral antigens, which occurred during a passage through X-irradiated hosts. The new population of MuLV− cells may have emerged by immunoselection of nonantigenic, less vulnerable cells that were either pre-existant in the general population or appeared as a result of antigenic modulation. Defined as the phenotypic suppression of a surface antigen, occurring as a result of the cell's exposure to a specific antibody in the absence of complement[6], antigenic modulation has been reported in relation to various virus-associated[3,6-11] and histocompatibility[11-13] antigens. We have reported the antigenic deletion of MuLV antigens on lymphoma cells passaged through rats that have been rendered specifically unresponsive to these antigens at birth[3-5] as well as loss and recovery of MuLV antigens by *in vivo* and *in vitro* cultivation[9]. The importance of such phenomena lies in their possible relation to the mechanisms by which allografts and tumour cells can be unrecognised and escape immunological destruction[14-15].

In the work reported here, we are inclined to believe that the deletion of membrane viral antigens is the result of antigenic modulation, based on evidence from immunofluorescence that the membrane alterations occurred stepwise (patching-capping deletion), as well as on evidence from preliminary experiments (to be reported later), showing that the antigenic changes were reversible *in vitro*.

Table 2 Antigenicity and transplantability of lymphoma cells in relation to time after irradiation

Time after* irradiation (d)	MIF†		Transplantation‡

48– 61	2	2	2/4	50
63–102	0	13	13/13	100

*Time interval between irradiation/transplantation and assays.
†Membrane immunofluorescence: no. of rats with + or −MIF.
‡T/TR = permanent tumours/transplanted tumours.

The occurrence of cellular antigenic modulation after irradiation might be related to a special state of immune imbalance created by the effect of X-rays. T lymphocytes are more susceptible to radiation effects than B lymphocytes[16-18] and one result of X-irradiation is the creation of a temporary imbalance between the two major compartments of lymphoid cells. It is also possible that B cells are increased in the general circulation, not only in relative values but also in absolute amounts in compensation for the depletion of T cells or as a result of T-suppressor-cell destruction.

Table 1 Serial subcutaneous transplantation of GLV lymphoma from X-irradiated rats

Transplant generation	Treatment	Tumours*	Metastases†	Antigens‡	Antibodies§

§Titres of serum anti-MuLV antibodies determined by cytoplasmic indirect immunofluorescence on standard LT_1 tissue culture GLV-producing cells, as previously described[3]. Figures are means with the ranges in parentheses.

Antibody stimulation of tumour growth has been reported in T-cell depleted animals[19], and an excess of antibody in irradiated, B-cell-stimulated, recipients might explain the immune pressures that induce antigenic modulation.

In man, postoperative irradiation is used and credited with prevention of recurrent and metastatic tumours. But in the light of modern concepts of the role of immune surveillance in the control of tumours, the effect of X irradiation, one of the strongest immunosuppressants, has been reviewed critically. Retrospective[20] and prospective[21] studies of patients with breast cancer treated by radical mastectomy with or without postoperative irradiation showed marked increases in the number of lung and skin metastases in the former group, suggesting that radiotherapy, while effective in the control of local recurrences, might induce an increase in the number of distant metastases.

Whereas such adverse results are not entirely surprising in view of the immunodepressant effect of X irradiation, the mechanisms of its activity are not clear. Our experiments, demonstrating changes of lymphoma cells induced in X-irradiated hosts as a result of immunological imbalance, suggest a possible mechanism.

We thank Dr Earl Brant for help and advice in the radiation work, and Marianela Villaverde and Tove Bamberger for technical and secretarial help. This work was supported by a grant from the NCI.

Suppressor T-cell inactivation of a helper T-cell factor

THE ability of a subpopulation of T cells to inhibit both cellular and humoral responses is well documented[1,2]. These regulatory or suppressor T cells have been produced by both antigen-specific and nonspecific stimuli, and both antigen-specific and nonspecific suppressive mechanisms have been suggested. In various studies T cells, B cells and macrophages have all been implicated as the primary target of the suppressor cells. We[3,4] and others[5,6] have reported the nonspecific activation of both helper and suppressor murine T cells by concanavalin A (con A). The helper cell produces a nonantigen-specific mediator (NSM), of molecular weight 35,000, which can substitute for antigen-specific helper cells in the *in vitro* plaque-forming-cell (PFC) response of murine B cells to the antigen, sheep red blood cells (SRBC)[3,4]. We report here the inhibition of this response by con A-activated suppressor cells and present evidence that the mode of action of the suppressors in this system involves the inactivation of the helper factor, NSM, and not a direct effect on the responding B cells.

We initially observed that in cultures containing B cells, SRBC and NSM the anti-SRBC PFC response was severely suppressed by the addition of small numbers of spleen cells which had been activated by 48 h of culture with Con A. Extensive titrations of both the helper factor and the suppressor cells indicated a competitive relationship between the two. The results of a typical experiment are shown in Fig. 1. B cells cultured alone with SRBC produced no anti-SRBC PFC. An increasing PFC response was obtained with the addition of increasing amounts of NSM until saturation was reached. The addition of various numbers of suppressor cells to these cultures generated a series of titration lines roughly parallel to the control titration, but shifted so that the amount of NSM necessary to achieve a given response increased with the number of suppressors.

An apparent competition between con A-activated helper and suppressor T cells was originally reported by Scavulli and Dutton[7]. Because we used the cell-free helper factor, NSM, the possibility of a direct interaction between the helper and suppressor T cells seemed to be eliminated as an explanation for the competitive effect. Our results suggested instead either that con A-activated suppressor cells can

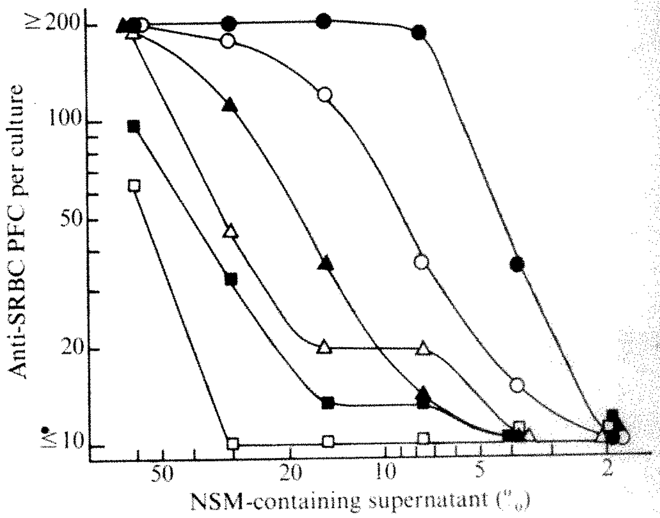

Fig. 1 Competition between NSM and suppressor cells. B cells were prepared from the spleens of BDF$_1$ mice (Jackson Laboratories) as previously described[3,4] using both an *in vivo* treatment with anti-thymocyte serum (Microbiological Associates) and an *in vitro* treatment with specific anti-T-cell serum and complement. Microcultures were prepared by modifications[3,4] of the methods of Mishell and Dutton[16]. Each culture well contained 2×10^5 B cells and 0.01% SRBC as the antigen in 0.1 ml of either medium or medium containing the various proportions indicated of an NSM-containing, 24-h supernatant from normal spleen cells cultured at 10^7 per ml with con A (4 μg ml^{-1})[3,4]; Residual con A had been removed from the supernatant by absorption with Sephadex G-200[3,4]. In addition microcultures contained either 0 (●), 7.5×10^2 (○), 1.5×10^3 (▲), 3.0×10^3 (△), 6.0×10^3 (■), or 1.2×10^4 (□) suppressor cells produced by culturing normal spleen cells for 48 h at 10^7 per ml with con A (4 μg ml^{-1}). After 4 d individual cultures were assayed for anti-SRBC PFC. Each point represents the average of the responses assayed in 12 identical cultures. In the absence of NSM all responses were less than 10 PFC per culture.

interact directly with NSM, or that they compete with NSM in their effects on B cells.

The possibility of a direct suppressive effect on B cells was eliminated in a second group of experiments. Several workers[8–12] had shown that B cells responding to SRBC were induced by the antigen to undergo at least one round of division in the absence of helper factors. Helper cells or factors were important in the response only after 24–48 h, when their addition was essential for the continued proliferation and differentiation of the responding B-cell clones to the point of antibody secretion. We looked at the effect of suppressor cells on this response when NSM was not added to cultures until 24 h after the initiation of the response by antigen (Fig. 2). The responses of control cultures were similar whether NSM was added at zero time or at 24 h. The results, however, clearly showed that the presence of suppressor cells throughout the culture period was not a sufficient condition for suppression, for suppression was not seen if the addition of NSM was delayed 24 h. This result eliminated the possibility of a direct inhibitory effect of the suppressor cells on B cells.

There are several possible explanations for the requirement that NSM must be present from the beginning of the response in order for suppression to be observed. The possibility that we explored further was that, because B cells do not develop the requirement for NSM until at least 24 h into the response, the presence of suppressor cells and NSM together during this period might lead to NSM inactivation. When added at 24 h, the NSM might interact with the then receptive B cells before its inactivation by suppressor cells.

To test the possibility that suppressor cells act directly on NSM we preincubated concentrated aliquots of NSM for 24 h alone or with various concentrations of suppressor cells. The cells were then removed by centrifugation, and the supernatants tested for NSM activity on B cells which had been cultured for 24 h with SRBC. As Fig. 3 shows, the NSM preparation preincubated alone produced a normal anti-SRBC response, whereas preincubation with increasing numbers of suppressor cells yielded successively less active supernatants. It should be noted that the ratios of suppressor cells to NSM in the preincubation step were similar to those which produced suppression in the experiments reported in Figs 1 and 2. These results indicated that the full activity of the suppressor cells could be accounted for by the direct elimination of NSM activity.

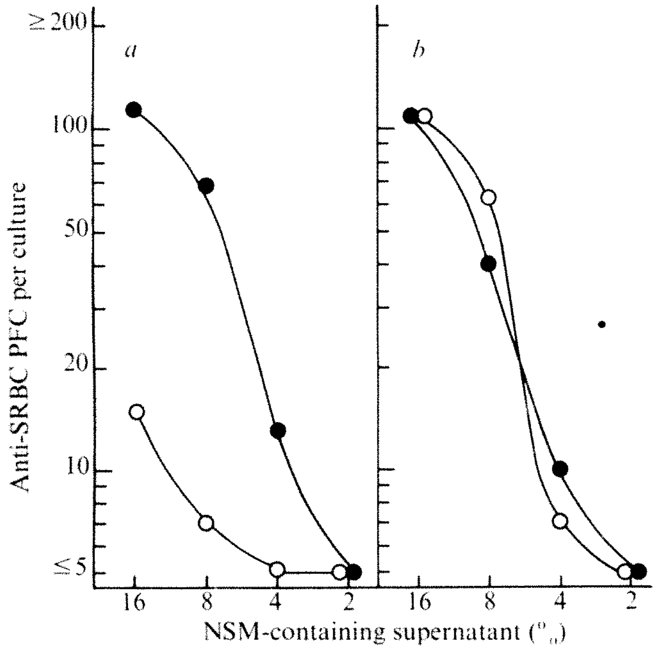

Fig. 2 Loss of suppression with the delayed addition of NSM. NSM containing supernatant, suppressor cells and B-cell cultures containing SRBC were prepared as in Fig. 1. *a*, A group of B-cell cultures received various proportions of NSM supernatant at time zero (●). A second identical group received in addition 2×10^3 suppressor cells at time zero (○). *b*, Same as (*a*) but the addition of NSM was delayed until 24 h. All cultures were assayed for anti-SRBC PFC on day 4. The results are pooled from two identical experiments. Each point is the average response of 24 identical cultures. In the absence of NSM all responses were less than 5 PFC per culture.

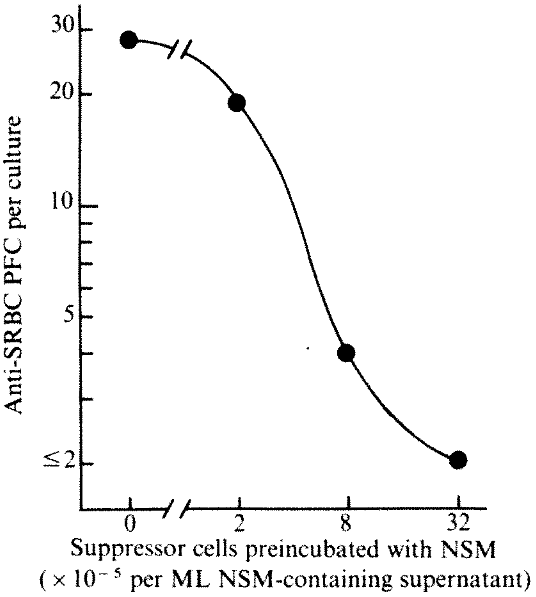

Fig. 3 Inactivation of NSM by preincubation with suppressor cells. Neat NSM-containing supernatant, prepared as in Fig. 1 was preincubated for 24 h at 37 °C either alone or with various concentrations of suppressor cells, prepared as in Fig. 1. B-cell cultures containing SRBC were prepared as in Fig. 1. After 24 h the various preincubated supernatants from which cells had been removed by centrifugation were added to the B-cell cultures to a final concentration of 10%. After an additional 3 d all cultures were assayed for anti-SRBC PFC. The results of four similar experiments were combined. Each point represents the average response of from 36 to 48 individual cultures. In the absence of NSM the response was less than 2 PFC per culture.

Several additional control experiments were performed. For example, the cell responsible for the NSM inactivation was shown to be eliminated by treatment with anti-T serum and complement whether before or after con A activation (data not shown). Typical results of a second control experiment are shown in Fig. 4. As expected, NSM preincubated with excess suppressor cells lost all activity. Preincubation of NSM with the same number of normal spleen cells, however, resulted in no loss of NSM activity, demonstrating the need for con A activation to produce the suppressor cells. In addition, the loss of NSM activity was not due to its masking by an inhibitory factor produced by the suppressor cells or to the conversion of NSM to an inhibitory factor, for either medium or NSM preincubated with suppressor cells had no effect on the activity of fresh NSM. These latter results also suggest that the loss of NSM activity was not through the action of a soluble degradative enzyme, but rather required direct interaction of the NSM with the suppressor cells. We are attempting to distinguish whether this interaction resulted simply in the stoichiometric absorption of NSM by a suppressor cell receptor or in its destruction at the cell surface.

In summary, our results indicate that the action of con A-activated suppressor cells on the response of B cells to the antigen, SRBC, and the helper factor, NSM, is through the inactivation of the NSM rather than a direct effect on B cells. They suggest that one mode of action of regulatory T cells is the control of the level of immunologically active mediators.

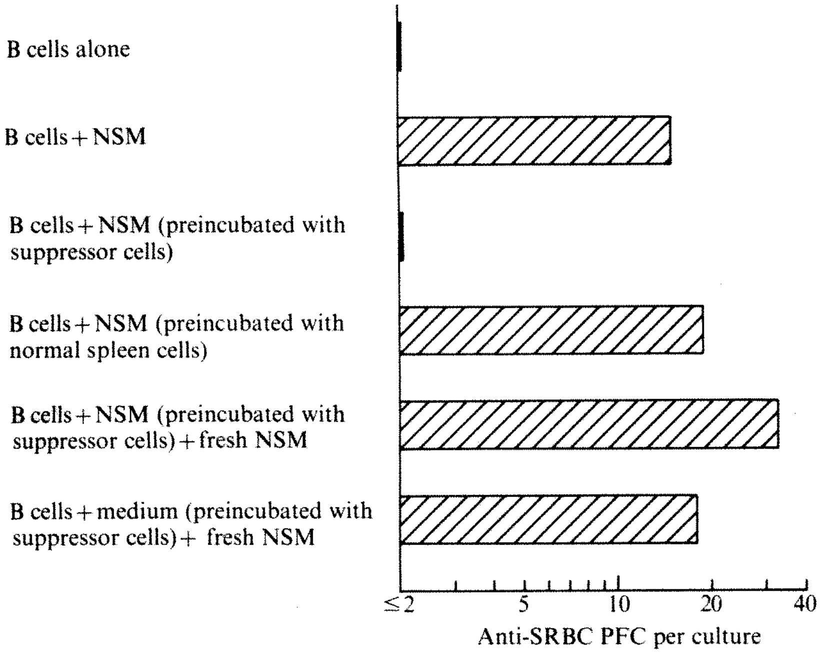

Fig. 4 Need for con A activation of the suppressor cells and the lack of the production of a soluble suppressive activity. NSM-containing supernatant, prepared as in Fig. 1, was preincubated for 24 h at 37 °C either alone or with 8×10^3 suppressor cells per ml or with 8×10^3 normal spleen cells per ml. In addition normal medium was preincubated with 8×10^3 suppressor cells per ml in the same conditions. B-cell cultures containing SRBC were prepared as in Fig. 1. After 24 h the various supernatants prepared as above were added to the B-cell cultures to a final concentration of 10%. Some cultures received in addition fresh NSM supernatant to final concentration of 10%. After a further 3 d all cultures were assayed for anti-SRBC PFC. Each bar represents the average response of twelve identical cultures.

Our results are somewhat at odds with those of Pierce *et al.*[13,14], who have proposed that the activity of con A-activated suppressor cells is accounted for by the production of a factor, indistinguishable from macrophage migration inhibitory factor, whose mode of action is to cause normal macrophages to become suppressive. Perhaps macrophages stimulated in this manner also develop the ability to inactivate helper factors. Our results also raise a question concerning the clearly demonstrated ability of con A-activated suppressor cells to inhibit responses to thymus-independent antigens[3,4,15]. Because these responses presumably do not involve helper factors, the mechanism of suppression is unclear. A direct interaction between suppressor cells and this special type of antigen is an intriguing possibility; however, alternative suppressive mechanisms involving direct effects on B cells are also possible.

Androgen-modified expression compared with Y linkage of male specific antigen

SEVERAL recent results have led to a widely held view that the male specific antigen (MSA) is coded for by a structural gene on the Y chromosome, and because of this it is frequently termed H-Y (refs 1 and 2). Although a good case has been put forward for this conclusion, there are some data that conflict with this view and some arguments against the notion. These are presented here as a reminder that, as is so often the case with biological experiments, the Scottish verdict "not proven" holds.

Evidence in favour of a Y-linked structural locus for the MSA has led to a hypothesis that the Y-linked gene(s) required for testis development and the MSA structural locus are one and the same[3,4]. It is theorised that MSA acts as a partially diffusible hormone able to induce male gonal formation in coated XX cells and evidence for this mechanism has been presented for bovine freemartins[5]. But strong evidence has been presented against Y linkage of the MSA[6]. This is the observation that XX, *Sxr* (sex-reversed) males have MSA. In spite of cytogenetic studies involving various new staining techniques, there is no evidence for translocation Y material in XX, *Sxr* males[7,8] and the presence of MSA in XX, *Sxr* males is incompatible with Y linkage of the structural gene for MSA. Evidence for the presence of MSA in phenotypically female, XY, *Tfm* mice has been presented as evidence that the MSA is not a concomitant of maleness *per se* and, therefore, must be Y-linked. An alternative hypothesis states that the structural locus for the MSA is autosomal, that its expression is triggered by a male determinant normally controlled by a portion of the Y chromosome, and that apparent Y-linked allelic differences in the MSA are the reflection of altered levels of this Y-chromosome factor, due to allelic forms of the Y-chromosomal locus. *Sxr* could be a constitutive mutant of the autosomal locus normally induced by the Y-chromosome factor. According to this hypothesis, the evidence that MSA is present in phenotypically female *Tfm*/Y mice[9], which have high circulating levels of testosterone, provides the limitation that, if the

Table 1 Summary of Y-linked 'fertility' data

Characteristic	Strains compared	Evidence for Y linkage	Ref.
Mean sperm dimensions	Strains selected for large virus small body size	Paternal cytoplasmic effect or Y-linked effect	45
% Morphologically abnormal sperm	C57B1 (high) against CBA (low)	Portion of effect Y-linked	46
% Morphologically abnormal sperm	KE (high) against KP (low)	Portion of effect Y-linked	47
% Morphologically abnormal sperm (with fertility inversely correlated)	KE (high) against CBA (low)	Portion of effect Y-linked	48
Male behavioural differences	PHH against PHL	Y-linkage accounts for all the difference	49
Male aggression	DBA/1/Bg against CBA/FaCam (low)	Y-linkage or maternal effect	50
Adult testes size	SF (high) against CBA/FaCam (low)	41 % Explained by Y linkage	51

MSA is mediated by testosterone, the hormone does not act through a target organ mechanism limited to males (the cytosol testosterone receptor thought to be altered in *Tfm*[10,11] is present in females as well as males[3,12]) This mechanism would already seem unlikely because of the presence of MSA on epidermal cells, where it is detected by skin grafting, and other tissues which are not primary testosterone targets

Two other aspects of research on the MSA may be responsible for part of the confusion. First, the work on MSA has been performed by skin grafting; only recently has serological detection of the MSA been possible[13]. The antigen detected with mouse sera cross reacts with cells from other mammals studied, including man[14], and even amphibia and birds, where the female heterogametic sex has the antigen[15]. Grafting techniques, however, have not established a MSA in man[16,17] or amphibia[18] but the lack of inbred strains in these species may be the problem, that is, it is not possible to make male-to-female grafts between individuals with otherwise identical genotypes. Immunological cross reactions between such widely divergent species are likely to be due to something other than a protein, for example, a carbohydrate or a steroid, or a protein whose function is extremely stable in evolution, such as histone IV. If one is to argue that the evolutionary conservation of the MSA reflect a conserved function, there is the problem that its function must be related to female sex determination in WW, WZ species. If the MSA is a protein coded for by the heterogametic sex chromosome, it might be simpler to postulate that it is a protein involved in the synthesis or packaging of the unique, heterogametic tandemly repeated DNA[19]. Second, differences in the MSA detected by skin grafting may not reflect different alleles but different loci, that is, there could be a MSA with a Y-linked structural gene and other MSA(s) which are autosome-linked and androgen-dependent.

The original evidence that the MSA locus was on the Y chromosome was of two sorts. First, teratoma lines maintained by *in vivo* passage have a tendency to lose the Y chromosome and apparently lose the MSA concurrently[20]. But the reported loss of the MSA in teratomas which had lost the Y chromosome depended on very few grafts; some Y-containing cells persisted in the accepted grafts; and the work was not confirmed[21]. Second, there are various strengths of the MSA, originally detected by skin grafting[22–24] and possibly found serologically[13], which are Y-linked Other workers, however, have not been able to reproduce some of the results suggesing alternative forms of a Y-linked antigen[25–26]. More recently, a dose relationship between the number of Y chromosomes and the amount of seriologically detected MSA in humans has been used to argue for Y-linkage of the MSA[27]. Studies on humans have also shown MSA in XX males with no detectable XY cell line[28], a situation analogous to *Sxr*, XX mice. Thus, the data are also highly compatible with the interpretation that MSA is a concomitant of maleness which can occur occasionally in the absence of a Y chromosome, for example, polled in goats[29], as femaleness can occasionally ccur in the presence of a Y chromosome[30]

There is a variety of evidence to suggest that the MSA depends on androgens for its expression. Neonatal orchiectomy of C57B1/6 males leads to prolonged, or even permanent, survial of the adults' skin on females of the same strain[31,32], while neonatal male skin grafts allowed to develop after being transplanted to adult females do not reach normal adult male skin immunogenicity for secondary female recipients until after more than 100 d[33]. Furthermore, female responsiveness to male skin grafts is specifically depressed by testosterone injections started at birth[34], while skin from males pretreated with a non-functional analogue of testosterone, cyproterone acetate, has prolonged survival on females[35]. Thus, expression of the MSA is not complete in these situations, in spite of the presence of the Y chromosome. Testosterone, however, can have inhibitory effects on the immune response[36] and this could explain effects on female responsiveness.

The observation that MSA expression can be modified by *H–2* region-linked genes[37], which is also controversial[34], could be explained by a previously described *H–2*-linked effect on testosterone levels[38,39]. (The effect of *H–2* on MSA expression seems to be separate from the role of *H–2* in the specification of the MSA target cell complex for cell-mediated cytolysis[40], a role *H–2* antigens also play with hapten or virus-induced cell surface antigens[41–43].) It should be added that the anti-androgenic steroid also reduced expression of *H–3* and *H–2* antigens, as measured by the surival of skin grafts from treated males transplanted across those barriers[44]. The latter result suggests that androgens could easily play an important role in the expression of antigens not linked to the Y chromosome, including the MSA.

There are various Y-linked differences among males of different inbred strains, and most of these putative Y-linked phenotypic differences could be secondary to levels of androgen (Table 1). The difference which should be most clearly related to androgen levels is that of testes size; 41% of the difference between CBA/FaCa and SF strains was Y-linked[51]. Thus, if the original data suggesting Y-linked alleles for the MSA are correct, these may be explicable as secondary effects of Y-linked differences in androgen levels. The Y chromosome "switch" for male-determination is postulated to have several alternative levels of expression. The apparent double dose of Y antigen in human males with two Y chromosomes[27] is also compatible with this hypothesis

If the MSA is actually controlled by an autosomal locus but modified by androgen activity (with the latter possibly showing allelic variation controlled by the Y chromosome), the presence of MSA in phenotypically female, *Tfm*, XY mice[9] argues that the action of androgens on the MSA is not through a mechanism limited to testosterone target organs of males Testosterone seems to have important functions in female reproduction[52] and to be involved in protein synthesis in the female liver[53]. The latter function of androgen in females is mediated by microsomal membrane testosterone receptors[54] which are under hypothalmic control[55]. There are other examples of steroid hormone function which are not mediated by cytosol receptor-nuclear translocation mechanisms. There is evidence that oestrogen[56] and glucocorticoids[57–58] have direct effects on intracellular cyclic AMP levels while oestrogen releases histamine from the rat uterus[59] and progesterone mediates effects on frog oocyte differentiation which involve an effect on the outer surface of the cell membrane, without a requirement for entrance of the hormone into the cell[60]. Thus there are androgen responses which are not male, target-organ-limited, but if they are responsible for MSA expression they should not all be shared by the female. If they were, MSA should not be detectable because the antigen should be produced in the females and they would be tolerant. Rather, it is assumed that various androgen functions, some of the target organ type and some mediated by other pathways but male-limited, are "turned on" in the male by the Y-linked trigger which may have a primary effect on one autosomal locus such as the *Sxr* locus. Then it would be possible that the *Sxr* locus product is MSA[6], while its expression would normally be controlled by a Y chromosome.

There are two major arguments against this alternative hypothesis. First, there is the reported detection of antigen cross reacting with murine MSA in females of birds and reptiles where the female is the heterogametic sex[15]. There is also evidence that female-to-male grafts are rejected in chickens[61]. But this creates a theoretical dilemma: if the antigen is a protein then it has been uniquely stable in evolution when its function has changed to become female determinitive while if it is not a protein, the argument that Y-linked allelic forms demonstrate a structural locus on the Y chrososome is much more tenuous. Second, there is the apparent finding of MSA on putative XY mouse embryos at the eight-cell stage[62]. This cannot be explained by secondary effects of maleness but needs further confirmation: embryos were classed as "dead" if only one cell was lysed and in no case were more than five cells lysed. The 50% "death" of eight-cell embryos can be explained just as readily by assuming that all the embryonic cells are equally sensitive to antibody plus complement. If the probability that any given cell will be lysed is only 0.083, then 50% of the embryos will remain unaffected, while the remainder should have one or more lysed cells, the number of cells lysed per eight-cell embryo following a binominal distribution. Such a distribution predicts the presence of very few embryos with four or more dead cells. Although the actual data have not been presented, larger than expected numbers of embryos with four or more dead cells might simply reflect some degree of co-operativity, with the death of one cell rendering the adjacent cells more susceptible to lysis.

Specific binding of a synthetic oligodeoxyribonucleotide to yeast cytochrome *c* mRNA

THE investigation of specific messenger RNAs in terms of sequence analysis and of the control of their synthesis, processing, translation and degradation is one of the major interests of modern molecular biology. These studies have been possible so far in only the few cases where a cell type is known to synthesise predominantly one species of protein. Since most mRNAs are chemically similar, differing only in size and sequence, it has been difficult to purify them by conventional methods. Given the amino acid sequence of a protein, one can use the genetic code to deduce a sequence of nucleotides in a specific region of the mRNA and then synthesise an oligodeoxyribonucleotide complementary to that region[1–4]. We have chosen to investigate the yeast iso-1 cytochrome *c* mRNA as a model system for the use of synthetic oligonucleotides as specific probes of eucaryotic mRNA structure and function. The genetics of yeast iso-1 cytochrome *c* has been studied in great detail by Sherman, Stewart and co-workers[5,6], who have determined the sequence of 44 nucleotides of the mRNA from the analysis of altered cytochromes produced by a series of double frameshift mutants. In addition, a number of well defined deletion mutants are available within this region. The pentadecadeoxyribonucleotide (15-mer) that we decided to synthesise, 5′-d(A-G-C-A-C-C-T-T-T-C-T-T-A-G-C)3′ is complementary to nucleotides 25–39 of the cytochrome *c* mRNA (Fig. 1). This sequence was chosen because it is relatively easy to synthesise, should form a very stable hybrid with mRNA, and is close to the 5′ end of the coding region of the mRNA. A known deletion mutation covers this region, yet allows the production of a functional cytochrome *c* in normal amounts[5,6], and thus provides an excellent control for hybridisation experiments. We have been able to show that the

Fig. 1 Amino acid sequence of yeast iso-1 cytochrome *c* (*a*), and nucleotide sequence of its mRNA (*b*,) with the complementary DNA sequence *c*. The boxed-in area represents the synthetic 15-mer.

synthetic 15-mer does indeed bind specifically to the expected region of the mRNA, and therefore should be useful as a specific probe for the study of this mRNA.

The chemical synthesis of the pentadecanucleotide was by the modified phosphotriester method of Narang and co-workers[7,8]. Recent developments in this approach to synthesis, such as the introduction of new reagents for phosphorylation and condensation, have greatly reduced the time required to synthesise oligonucleotides 12–21 nucleotides 3 long. Our synthesis proceeded in three stages. First, completely protected mononucleotide 3′ phosphates were prepared according to the procedures of Narang and co-workers[8,10] except that the methylbutyryl group was used for the protection of the amino group of deoxyguanosine[11], and the 3′ OH of the primer was protected by acetylation[12]. Secondly, the monomers were condensed into di- and tri-nucleotides as described earlier[8,10]. Finally, the five trinucleotides were assembled using mesitylenesulfonyltetrazole as a condensing reagent[13,14]. The final product was deblocked and the 15-mer purified on a Sephadex G-50 column followed by chromotography on a DEAE-cellulose column in 7 M urea with a final yield of 10 μmol.

We have confirmed the sequence of the synthetic oligonucleotide by direct sequence analysis (Fig. 2). The 15-mer was labelled with ^{32}P at the 5′-end with polynucleotide kinase[15], or at the 3′-end with terminal transferase[16]. The labelled material was partially digested with venom or spleen phosphodiesterase, and mapped by electrophoresis on Cellogel strips followed by homochromatography[15,17,18]. Each map consists of a series of spots which represent the products of partial digestion of the starting material. The mobility shift of each successive spot is characteristic of the added nucleotide[18]. In all cases the mobility shifts are as expected. Furthermore, 5′-end analysis shows that >95% of the 5′-nucleotide is A and the 3′ nucleotide is C.

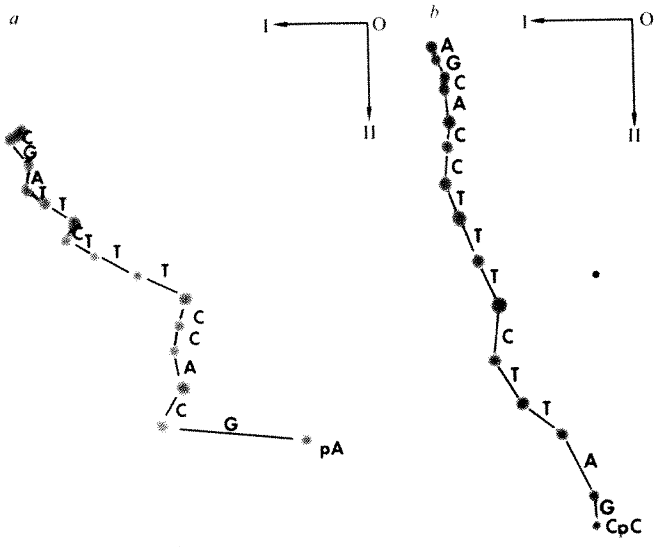

Fig. 2 *a*, Two-dimensional homochromatography of a partial venom phosphodiesterase digest of the synthetic pentadecanucleotide d(^{32}pA-G-C-A-C-C-T-T-T-C-T-T-A-G-C). Dimension I, electrophoresis on cellulose acetate strip (Cellogel, Reeve-Angel), *p*H 3.5 at 2000 V for 40 min. Dimension II, homochromatography on DEAE-cellulose plate (20 × 20 cm), with Homo-mix IV[15]. *b*, Two-dimensional homochromatography of a partial spleen phosphodiesterase digest of the 16-mer d(A-G-C-A-C-C-T-T-T-C-T-T-A-G-C)^{32}prC produced by transferase labelling with (α – ^{32}P)rCTP of synthetic 15-mer. Dimensions are as in Fig. 2*a* except that homochromatography was done on a 20 × 40-cm plate with Homo-mix III[15]. The migration of the spots is less in the electrophoresis dimension because there is an -OH group at both the 5′-end and the 3′-end of the oligonucleotides.

Hybridization of the 15-mer to the cytochrome *c* mRNA can be detected by incubating bulk mRNA with an excess of the ^{32}P-labelled oligonucleotide under the appropriate conditions, and then separating the free from the bound 15-mer by chromatography on Sephadex G-75 or by electrophoresis in a 5% polyacrylamide gel. Both methods gave the same results but the latter method is most suitable for the simultaneous analysis of a large number of samples. We found that most of the binding to mRNA (>80%) from derepressed wild type yeast (grown with aeration on ethanol) is due to specific hybridisation to iso-1 cytochrome *c* mRNA. In control experiments, the binding of 15-mer to mRNA from either repressed wild type cells (grown under nitrogen with high glucose), or from derepressed cells which carry a deletion of the complementary region, is reduced to less than 20% of the binding to mRNA from derepressed wild type cells. The amount of 15-mer bound to wild-type mRNA is in direct proportion to the amount of mRNA present (data not shown). When the amount of mRNA in a hybridisation reaction

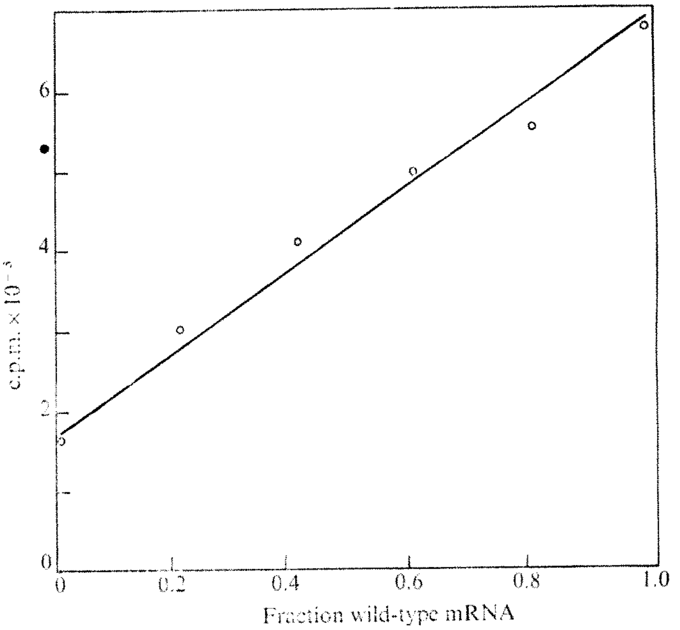

Fig. 3 Specific hybridisation between synthetic (^{32}P)15-mer and yeast cytochrome *c* mRNA. Total RNA was isolated by breaking chilled yeast cells in a Braun homogeniser in the presence of phenol, followed by centrifugation and ethanol precipitation of the aqueous layer. Electrophoretic analysis of this RNA showed very sharp ribosomal RNA bands with no evidence of any degradation products. The mRNA fraction was isolated from the total RNA on poly-U Sepharose column[2]. 1.0 pmol of (^{32}P)15-mer and 50 μg of mRNA were dissolved in 50 μl of H-buffer (0.1 M Nacl, 0.01 M Tris-Cl, *p*H7.5, 0.001 M EDTA, 0.05% SDS). The amount of mRNA from derepressed wild-type cells (stain D311-3A, *a*, *his1*, *trp2*, *lys2*) was varied from 0 to 50 μg, with each sample made up to 50 μg total with mRNA from derepressed deletion mutant cells (strain B2185, aCYC-1-183-AD, *his1*, *trp2*, *lys2*). Strains of yeast were a gift of Dr Fred Sherman. The reaction mixtures were incubated at 37 °C for 18 h, at which time 10 μl of loading dye (60% sucrose, 0.2% bromophenol blue) was added to each sample. Electrophoresis was carried out for 3 h at 3 V/cm on a 5% polyacrylamide gel (5% cross-linking with *bis*-acrylamide). All mRNA and bound primer was contained in an area within 0.5 cm from the origin, which was cut out and counted. Approximately 0.1–1.0% of the input labelled primer was bound to mRNA.

is made up to a constant amount with mRNA from deletion mutant cells, the amount of 15-mer bound increases in direct proportion to the amount of mRNA from wild type cells (Fig. 3). Therefore, the 15-mer is specifically hybridizing to the cytochrome *c* mRNA.

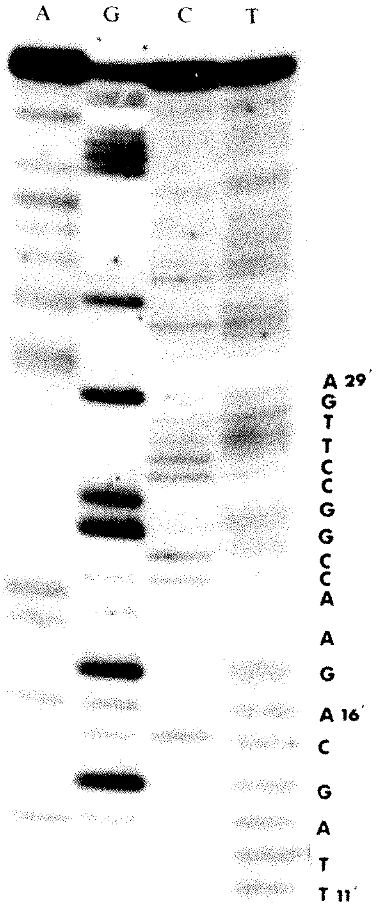

Fig. 4 Enzymatic extension of 15-mer primer hybridised to yeast cytochrome *c* mRNA. 5 mg of mRNA was incubated with 500 pmol of 5′(^{32}P)15-mer (1000 mCi μmol^{-1}) in 5.0 ml of H-buffer at 37 °C for 44 h. The primer-mRNA hybrid (1.1 × 10^6 c.p.m.) was separated from free primer on a Sephadex G-75 superfine column (2.4 × 35 cm) in 0.1 M NaCl, 0.01 M Tris-Cl pH 7.5. The 15-mer primer was extended by the incorporation of unlabelled dNTPs as follows[19]. The solution containing the primer-mRNA hybrid (11.0 ml) was adjusted to a final concentration of 25 mM HEPES buffer (pH 7.5), 1 mM $MnCl_2$, and 5 μM of all four dNTPs. *E. coli* DNA polymerase I (100 units) was added and the reaction allowed to proceed at 1.5 °C for 4 h. The NaCl concentration was adjusted to 0.3 M and 2 vol. of ethanol were added. The mixture was chilled to −20 °C for 30 min and centrifuged at 10,000 r.p.m. in an HB-4 rotor for 20 min. The pellet, which contained 99% of the radioactivity, was dissolved in 0.3 ml of 0.3 N NaOH and incubated at 37 °C for 16 h to hydrolyse the RNA. To fractionate the labelled extended primer, the sample was loaded on a 20 × 20 × 0.3 cm polyacrylamide gel (10% acrylamide with 5% cross-linking, 7 M urea, 50 mM Tris-borate, pH 8.3) and electrophoresed at 400 V until the bromophenol blue had migrated 37 cm. The gel was then autoradiographed, the labelled bands eluted, concentrated on a DEAE-cellulose column, eluted with 2 M NaCl, and ethanol precipitated. The products of the primer extension reaction were sequenced by the chemical method of Gilbert and Maxam[20]. A-specific cleavage is obtained by partial purine methylation with dimethylsulphate, preferential depurination in dilute HCl, followed by chain cleavage with alkali. G-specific cleavage is obtained by partial methylation as above, followed by chain cleavage with piperidine. C- and T-specific digestions are obtained by partial hydrazinolysis (in the presence of 1 M NaCl for a C-specific reaction) followed by piperdine treatment to break the chain. The products of these four base specific partial digestions are separated on four lanes of a polyacrylamide slab gel (20% with 3% crosslinking, 7 M urea, 50 mM Tris-borate, pH 8.3). The autoradiograph of such a gel is shown above. The sequence is deduced from the presence of specific bands on each of the four lanes.

We have sequenced a short region adjacent to the binding site of the 15-mer as further proof that the 15-mer binds to the expected region of the yeast cytochrome *c* mRNA. DNA polymerase I will extend a DNA primer on a RNA template[19] in the presence of Mn^{2+} in place of Mg^{2+}. When 5′-(^{32}P) 15-mer bound to mRNA was extended under these conditions, a series of products was obtained which were separated by polyacrylamide gel electrophoresis in the presence of 7 M urea. The length of these products as determined by comparison with single stranded DNA markers ranged from 15 to approximately 120 nucleotides, implying the presence of at least 80 nucleotides proximal to the initiation codon of this mRNA. Sequence analysis of the major bands by the new chemical technique of Gilbert and Maxam[20] has shown that the sequence of the short products is part of the sequence of the long products. The 14 nucleotide sequence which we have determined (Fig. 4), 5′-d(A-G-A-A-C-C-G-G-C-C-T-T-G-A)3′, confirms the sequence Sherman and Stewart[5] determined by genetic analysis (Fig. 1 *b* and *c*). This provides additional evidence that the synthetic 15-mer is binding specifically to the expected site on the yeast iso-1 cytochrome *c* mRNA.

We are extending our studies to determine the sequence in the regulatory region of this yeast mRNA. The use of synthetic oligonucleotides as specific probes will make it possible to study many mRNAs which could not otherwise be approached.

A. maxam and W. Gilbert have kindly provided us with advice and a detailed protocol on their DNA sequencing method prior to publication. This work was supported by grants from the NSF, the ERDA and the US NIH.

Anomaly in the γ chain heterogeneity of the newborn

THE two types of γ chain in human foetal haemoglobin (HbF) are the products of nonallelic structural genes and have either glycine ($^{G}\gamma$ type) or alanine ($^{A}\gamma$ type) in position 136 (ref. 1). Although the examination of 108 cord blood samples from worldwide sources showed 102 to have a $^{G}\gamma$: $^{A}\gamma$ ratio within a relatively narrow range, one had a low ratio and five a high ratio[2]. It seemed possible that

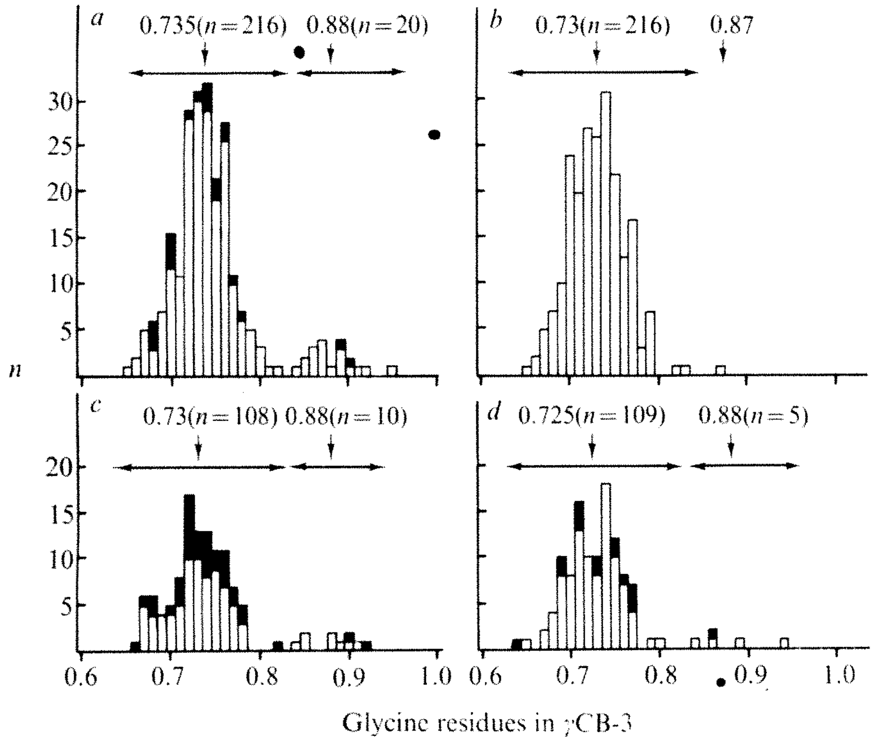

Fig. 1 Distribution of glycine residues of γCB-3 from the cord bloods of black and Caucasian newborns from different areas. Open columns denote data from newborns without haemoglobinopathy, and black columns denote data from HbS- and/or HbC-containing samples. *a*, Burke County blacks; *b*, Caucasians; *c*, Ghana blacks; *d*, Los Angeles blacks.

analytical error was responsible for these extreme values. But as we studied cord blood from normal black babies of residents from Burke County, Georgia, where an abnormal HbF (designated F_X (ref. 3)) has been detected repeatedly, we observed high ratios in further samples. The present study of almost 700 cord bloods has detected the high $^{G}\gamma : {}^{A}\gamma$ ratio in about 7.5% of samples from black newborns as compared with perhaps 0.5% from Caucasian infants.

The nonallelic γ genes are found worldwide and are not limited to specific ethnic groups or geographical areas[2]. Experimentally, the heterogeneity is best determined by cleaving the HbF with cyanogen bromide, isolating peptide γCB-3, and making an amino acid analysis for glycine and alanine according to the procedure described previously[1]. If the residues of glycine are integral at 1 or 0 and alanine at 2 or 3, the $^{G}\gamma$ or $^{A}\gamma$ chains alone are present in the HbF; a nonintegral number denotes a mixture. It is simplest to discuss results in terms of 'glycine values' rather than the $^{G}\gamma : {}^{A}\gamma$ ratio. Thus, in the initial study (2), 102 samples had glycine values between 0.65 and 0.79 residue; one was very low at 0.52 and five were above 0.8 residue.

The initial sampling of our extended study included only black children from Burke County. Subsequently, the survey was expanded to include blacks and whites from the Los Angeles area, blacks from Ghana, and whites from the Augusta area and from Malta.

That analytical error was not responsible for higher values was evident from reproducible data of 11 duplicate analyses which agreed with one exception within 0.05 residues as expected[4].

The data are summarised in Fig. 1. Clearly the anomaly manifests itself almost exclusively in black infants of whom 35 (of 468 studied) have glycine values above 0.82 residue in contrast to Caucasian infants of whom perhaps only one (of 217 studied) has the effect. The seemingly different incidence of 8.5% among Burke County as well as Ghana black babies compared with 4.4% in Los Angeles area black newborns may be attributed to more settled and less migratory communities in Burke County and Ghana compared with the more cosmopolitan sources of blacks in the Los Angeles area. The incidence of the anomaly in infants with HbS and/or HbC is 7.1% (five out of 71 infants), accords with the general incidence and suggests no relationship to an abnormal β gene.

Newborns with the anomaly are healthy babies without haematological problems. The range and average of alkali resistant haemoglobin by the Betke method[5] was not significantly different in newborns who had glycine values above or below 0.82 residue. All nine mothers and fathers of newborns with the anomaly who were studied had normal haematological indices and percentages of HbA_2 in the normal range of 1.7–3.7% (ref. 6). Two mothers and one father had sickle cell trait, one father had AC trait, and one mother had a slightly elevated level of Hb-F (Hb-F_{AD} : 4.1%).

It has been postulated that there may be as many as four structural γ chain loci (two $^{G}\gamma$ and two $^{A}\gamma$ loci (ref. 3)). Recent evidence suggests only two or three loci[7]. Several regulatory factors seem to be interspersed among the complex of β, γ and δ genes to control the production of protein by each gene[8]. Neither the nature nor the mode of action of these regulatory factors is known. Perhaps, the anomaly exerts its action either by increasing the production of the gene(s) for the $^{G}\gamma$ chains or vice versa by decreasing the activity of gene(s) for the $^{A}\gamma$ chain. Incomplete investigations suggest that the anomaly is hereditary.

As the HbF decreases postnatally until only traces of HbF remain in the adult, the glycine value also changes from approximately 0.73 in the infant to 0.4 (range about 0.25–0.55) in the adult[9]. Does a high glycine value at birth remain high or does it change to the adult range? Conversely, can a 'normal' glycine value of about 0.7 at birth remain unchanged? It has indeed been observed in a newborn with sickle cell anaemia that the 'normal' glycine value did not fall to the adult range[10]. Perhaps the anomaly reported here is responsible for those adult cases of sickle cell anaemia in which, unexpectedly, the glycine value falls in the newborn range rather than in the adult range[11,12]. Whether or not the recently reported $^{T}\gamma$ chain[13] is involved remains to be determined. These problems are under investigation.

Evidence for localisation of genes for human α-globin on the long arm of chromosome 4

There is disagreement about the site of the human haemoglobin structural genes, mapping of which has been attempted by *in situ* hybridisation[1–4] and family studies[5,6] After *in situ* hybridisation of human metaphase chromosomes with radioactive globin mRNA Price *et al.*[1] suggested that the haemoglobin structural genes are located on the long arm of chromosome 2 and on the long arm of a B-group chromosome, the latter carrying the genes for β, γ and δ chains. Their approach was criticised because of the low specific activity of the ^{3}H-mRNA assay used[7,8], but Atwood *et al.*[2] and Price and Hirschhorn[3,4] confirmed the original assignments using human complementary DNA (cDNA). Finally it was decided that the B-group chromosome that carries haemoglobin loci is chromosome 4[3,4]. Family studies gave results consistent with loose linkage between the locus of the MN blood group and β-thalassaemia. The MN blood group has been mapped tentatively on the long arm of chromosome 2 or on the distal end of the long arm of chromosome 4 (refs 9, 10). But the localisation of the MN system on 2q is inconsistent with data from family studies[11–13], and the distal segment of 4q has been considered more probable[11]. For similar reasons the β-globin locus has been mapped tentatively on chromosome 4 (ref. 5). We report here a study of globin synthesis which confirms that chromosome 4 is the site of the structural gene for α-globin.

We used reticulocytes from patients with congenital aberrations of chromosome 4, which had been demonstrated by R, T, and BUdR-acridine orange banding[14,15]. Case 1 (ref. 16) had duplication 4q28→ 4qter on the long arm of chromosome 2, associated with monosomy 2qter. The chromosomal formula was 46, XY, der (2), dup 4q, t(2;4) (q37; q28). In the healthy mother the same chromosome unbalance was detected in 10% of cells. Case 2 (ref. 16) showed duplication 4q28 → 4qter resulting from maternal translocation t(4; 18) (q28; q22), and was associated with monosomy 18qter. The chromosome designation was 48, XY, der(18), dup 4q, t(4;18) (q28;q22). Case 3 (ref. 16) displayed a "mirror" duplication of chromosome 4 from band q25 to band q34. The designation was 46, XX, der (4), 4qter → 4q 34: : 4q 34 → 4q25: : 4q 34 → qter. Case 4 (ref. 17) was carrier of duplication 4p13 → 4p16, associated with monosomy for the iuxta telomeric region of the long arm of chromosome 4. The designation was 46, XX, rec (4) dup p, inv(4)(p13;q35). The aberrant chromosome was interpreted as an aneusomic recombinant from the father who was heterozygous for a pericentric inversion of chromosome 4.

Red blood cells were drawn, washed and incubated for 1 h with S/^{3}Hleucine, as described by Clegg *et al.*[19] and modified by Riede[20]. Radioactivity and absorbance determinations and specific activity was calculated as described before[18].

As Table 1 shows, results differing significantly from control values were obtained with cases 1, 2 and 3. Two globin synthesis determinations (cases 1 and 3) were also carried out by Dr A. Fantoni (CNEN, Rome), who obtained ratios of synthesis α and β of 1.4 for case 1 and 0.79 for case 3.

Since red cell morphology and haemoglobin A$_2$ levels of the four patients, and their parents were normal, we concluded that cases 1, 2 and 3 had unbalanced globin synthesis of non-thalassaemic origin (pseudo-β-thalassaemia in case 1 and 2, and pseudo-α-thalassaemia in case 3).

Human α and β globins are normally synthesised in equal quantities. But duplication of a chromosome fragment including one of the two globin genes could result in increased production of the globin encoded by the duplicated fragment, with consequent unbalanced globin synthesis.

In cases 1 and 2 part of the long arm of chromosome 4 (bands 28 to 35 included) was duplicated; in both cases an excess of α-globin synthesis was observed. In case 1 the ratio of α/β synthesis was 1.45, which was very close to expectation in erythroid cells with three doses of functional α genes instead of two. Therefore it seemed reasonable to postulate for the diploid cells of this patient the presence of two genes for β globin and, due to chromosome duplication, one additional dose of genes for α globin. Case 2, although morphologically identical to case 1, showed an excess of α-globin synthesis smaller than expected for functional trisomy of the α-globin genetic region. It is possible that in this case the translocated fragment was somehow less active in globin synthesis than normal. Anyway, both cases suggest the localisation of the genes for α-globin on the long arm of chromosome 4 (from band 28 to 35). Band q35 is excluded by the data obtained for case 4 in which this region was deleted and the ratio of α/β globin synthesis was 1.0.

The chromosome abnormality of case 3 was the duplication and inversion of the long arm of chromosome 4 from band 25 to 34, including the same region duplicated in cases 1 and 2. In case 3, however, the ratio of synthesis of α and β globins was significantly below unity.

Observations of case 3 (personal communication from B. Dutrillaux) have shown that in 50–60% of lymphocytes cultivated in the presence of BUdR the long arm of the rearranged chromosome 4 is uncoiled and less fluorescent after acridine-orange staining This suggests the genetic inactivation of the long arm of the chromosome. The suggestion is derived from studies correlating BUdR uncoiling and genetic inactivation in translocations involving the X chromosome[22–27]. In our case despiralisation could involve the segment carrying the α genes, resulting in their inactivation. The erythroid cells of the subject could be therefore a mosaic of two populations, one with three and the other (that with despiralisation) with one

†Data obtained in a different laboratory, by a different technique.

dose of functional α-globin gene. This would explain the slight defect of α-globin synthesis which we found. The cell population with α-gene inactivation should have a pronounced defect of α-globin synthesis (relative to β-globin synthesis) with consequent accumulation of β_4 tetramers (HbH).

A proportion of the red cells of this subject should therefore contain inclusion bodies. It has not yet been possible to demonstrate such inclusion bodies.

Duplication of the α-globin structural genes has been shown in man[27]. It seems reasonable that the type of duplication fixed by evolution has allowed a balance between α and not α-globin chains; on the contrary this balance has not been respected in the chromosomal aberrations we have studied. On the other hand there is no evidence of chromosomal rearrangements deactivating the regulatory mechanisms of synthesis of structural genes, as observed in patients affected by Down's syndrome (Conconi and Del Senno, unpublished observations).

On the contrary there is considerable evidence for a dosage effect in the case of aneuploidy.

Vitamin A receptors in normal and dystrophic human retina

Vitamin A is necessary for normal development and functioning of most tissues of the body[1,2]. It is uniquely important for the retina in that, in addition to its possible general role in cellular metabolism, it participates in the visual process as the prosthetic unit for rhodopsin. This takes place in specialised regions of the photoreceptor cell called rod outer segments (ROS). Little is known, however, about uptake, binding and translocation of retinol, the alcohol form of vitamin A, in the photoreceptor unit. A specific 2S receptor for retinol of molecular weight about 17,000 has been described in several animal tissues[3,4]. Retinol receptors are also present in retina and pigment epithelium[5–9]. In addition, we have recently found that an 8S receptor is present in retina and brain of most but not all animal species tested[6]. We report here that normal human retina exhibits both a 2S and 8S binding species for retinol but that only the 2S species is observed in the retina of a patient who had retinitis pigmentosa (RP).

Eyes from two patients with normal retinae and from a patient with retinitis pigmentosa were maintained at 4 °C and used within 4 h of death. The two patients with normal retinae had died of heart disease (48 yr old) and acute lymphocytic leukaemia (17-yr old). The patient with retinitis pigmentosa died from bronchogenic carcinoma at 59 yr. He had extensive loss of peripheral vision, a characteristic finding in the disease. The retinitis pigmentosa in his family is consistent with either the X-linked intermediate or the autosomal dominant type. For histological and electron microscopic examination, a portion of the retinal tissue was fixed in 4% glutaraldehyde in 0.15 M phosphate buffer (pH 7.2) and sections were examined with a JEM-100B electron microscope. For biochemical analysis, retina and pigment epithelium–choroid layers were dissected individually, homogenised in 10 mM Tris buffer (*p*H 7.6, containing 1 mM EDTA, 10 mM KCl and 1mM dithiothreitol) and the 110,000*g* supernatant fraction (cytosol) was prepared[5]. Portions (0.25 ml) of the cytosol were incubated with 1×10^{-7} M ^{3}H-retinol (2.66 Ci mmol^{-1}, New England Nuclear) for 2 h at 4 °C. All operations involving vitamin A were performed in darkness or under dim red light. Samples were layered on 4.6 ml linear sucrose gradients (5–20% sucrose in the Tris buffer) and centrifuged 16 h at 243,000*g*. Approximately 35 fractions were collected per gradient and radioactivity determined as previously described[5]. Protein was measured by the method of Lowry *et al.*[10]. Concentrations were 6.1 and 5.0 mg protein ml^{-1} for normal and RP retinal cytosol samples and 5.6 and 2.0 mg protein ml^{-1} for normal and RP pigment epithelium–choroid cytosol.

Morphologically, the RP retina and pigment epithelium exhibited degenerative changes with marked loss of photoreceptor cells. Appreciable numbers of cone cells remained in the macula, but few of these had outer segments (Fig. 1*a*). Outer segments were detected only in the foveal area and were considerably disorganised as assessed by electron microscopy (Fig. 1*b*). Thus the sample was typical of advanced retinitis pigmentosa.

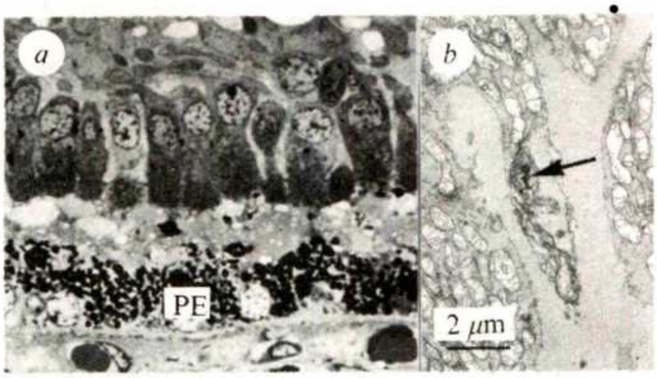

Fig. 1 *a*, Photoreceptor cells and pigment epithelial cells in the parafoveal area (× 660). Although the outer segments are generally missing in the area, cone cell bodies (C) are still present. The pigment epithelial cells (PE) contain abundant lipofuscin granules. *b*, Disorganised lamellar membranes within the outer segment of a cone cell are still recognisable (arrow) in the foveal area (× 4,320).

As assessed by sucrose density gradient centrifugation, two binding species for ^{3}H-retinol were observed in the cytosol fraction of normal human retina (Fig. 2*a*). Sedimentation coefficients are approximately 2S (peak at fraction 26) and 8S (peak at fraction 13). Under the present conditions, 180 and 900 fmol of vitamin A were bound per mg of total protein in the 2S and 8S peaks respectively. In the cytosol fraction of the RP retina, the 8S peak was completely absent. The 2S peak was comparable with that seen in the normal retina with 240 fmol of vitamin A bound per mg protein.

With normal pigment epithelium–choroid cytosol, a small 8S peak was seen along with a larger 2S peak (Fig. 2*b*). A 2S peak was observed in the cytosol fraction from the RP eye but the 8S peak seemed to be absent. Since the protein concentration was lower in the RP cytosol sample, binding in the 2S region of RP pigment epithelium–choroid cytosol was actually somewhat higher than in the normal case with 590 fmol and 800 fmol vitamin A bound per mg protein for normal and RP cytosol samples respectively. The 8S peak observed in the pigment epithelium–choroid preparation may be endogenous to the pigment epithelium or alternatively could be ascribed to ROS contamination. Even using the most favourable conditions, when normal retina is separated from pigment epithelium, a variable percentage of photoreceptor tips breaks off and remains entrapped in the microvilii of the pigment epithelium. In the RP eye, the lack of this small 8S peak may then be correlated with the virtual absence of ROS in the retina and gives supportive evidence for compartmentalisation or concentration of the 8S receptor species in ROS. Attempts to identify retinol receptors in purified ROS preparations have so far been unsuccessful, most probably because the receptors are soluble and are easily lost from ROS membranes during purification procedures.

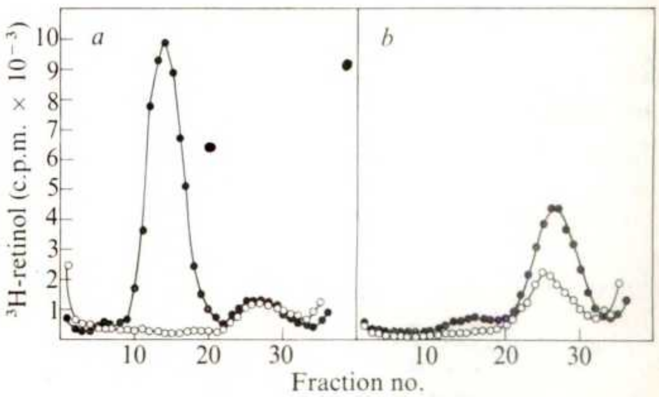

Fig. 2 *a*, Sucrose density gradient centrifugation patterns of human retinal cytosol fraction incubated with 0.1 μM ^{3}H-retinol. ●, Normal retina; ○, RP retina. *b*, Patterns with human pigment epithelium–choroid cytosol fraction incubated with 0.1 μM ^{3}H-retinol. ●, Normal pigment epithelium–choroid; ○, RP pigment epithelium–choroid.

These data indicate that not only does the human retina contain two distinct receptor species for retinol, but that these may be compartmentalised in different retinal areas. If one assumes that the 8S species is solely associated with outer segments, one would then expect an absence of this receptor species in the severely affected RP retina examined. In this way the RP retina serves as a model for a 'rodless' retina. Sequestering of the 8S species in an organelle as specialised as the photoreceptor unit would strongly implicate the receptor in the visual cycle, possibly as a transport vehicle for vitamin A between retina and pigment epithelium.

Lack of the 8S binding species may also be correlated with a specific biochemical abnormality resulting in or genetically linked to retinitis pigmentosa. Study of the receptors both qualitatively and quantitatively in retinae from young patients if they become available for research will clarify this point. In any event, the presence of at least two receptor species for retinol in normal human retina and the possible compartmentalisation of the 8S species in the photoreceptor unit suggest an important role for such receptors in normal retina functioning.

Identification of a membrane protein binding the retinol in retinal pigment epithelium

AVAILABLE experimental evidence indicates the primary role of retinal pigment epithelium (PE) in the uptake of retinol from the extravascular space of the choriocapillaris[1] and possibly in its transfer to and from the photoreceptors[2]. While the transport mechanism of retinol in plasma by the retinol-binding protein (RBP) is known in detail[3,4], only partial information is available on how circulating retinol is transferred from its carrier protein to PE. It has been shown[5] recently that iodinated human RBP binds specifically to isolated bovine PE and autoradiographic investigations[6] have suggested that the binding is confined to the choroidal surface of these cells. We have previously demonstrated[7] that isolated human and bovine PE actively binds ^{3}H-retinol only if this is present in the incubation medium as a complex with human RBP, and suggested that the interaction of circulating RBP with the cell membranes of PE is specific (G.M. and F.G., unpublished observations), and essential, for the active transport of retinol in these cells against a concentration gradient. We have now identified, in the plasma membranes of bovine PE incubated in the presence of ^{3}H-retinol-RBP, a binding protein for retinol; some evidence is presented which suggests that this membrane protein is different from plasma RBP.

The RBP used in these experiments was prepared from human plasma as described by Peterson and Berggard[4] and purified by affinity chromatography on prealbumin-coupled Sepharose 4B according to Vahlquist *et al.*[8] Retinol was then extracted from the lyophilised RBP with ethanol and ^{3}H-retinol (specific activity 2.4 Ci mmol^{-1}) substituted for the original chromophore in the apo-RBP following the procedure described in detail by Heller and Horwitz[9]. The reconstituted ^{3}H-retinol-RBP was again purified on the same affinity chromatography column in order to eliminate excess ^{3}H-retinol and possible residual apo-RBP by utilising the inability of retinol-free RBP to bind prealbumin[8,10].

PE was prepared from bovine eyes immediately after death as previously described[7]. Such PE preparations show no appreciable contamination by rod outer segments nor by choroidal remnants, and they actively synthesise proteins in short term (2 h) incubation experiments[7]. After the last washing the PE pellet was carefully resuspended in 2 ml of the same medium containing ^{3}H-retinol-RBP (0.1 nmol ml^{-1}) and incubated for 1 h at 37 °C in a water bath with occasional gentle stirring. At the end of the incubation period the cells were separated by centrifuging, washed twice in ice-cold unlabelled medium, homogenised in 1 ml of medium with a tight-fitting Teflon glass homogeniser and separated on a discontinuous sucrose gradient. By this method it was possible, as shown by electron microscopy of fixed samples of the different bands collected at the gradient interfaces, to separate the plasma membranes of PE clearly from the soluble cell sap and from the other cellular organelles. The gradient was then scanned at 280 nm and tested for radioactivity. The gradient pattern and the distribution of radioactivity of a typical experiment are reproduced in Fig. 1. Inspection of the figure shows clearly that radioactivity is practically limited to the two most superficial gradient bands, that is, those corresponding to the soluble cell sap and to the plasma membranes of PE. Although the ratio between turbidity and radioactivity is substantially similar for the two peaks, as much as 75% of the radioactivity is found in the plasma membrane fraction.

The fractions corresponding to this main peak were pooled and diluted with Krebs Ringer solution and the plasma membranes were collected by centrifuging at 35,000 r.p.m. in a SW40 rotor for 2 h. This washing procedure did not cause the removal of significant amounts of the membrane-bound retinol since only about 6% of the original radioactivity was found in the resulting supernatant fluid. The plasma membrane pellet was then dissolved in a detergent solution and analysed for protein and radioactivity distribution by polyacrylamide SDS electrophoresis (7.5–12% acrylamide). The gels were calibrated for molecular weight determination using serum albumin (molecular weight 40,000), soybean trypsin inhibitor (molecular weight 20,000), human RBP (molecular weight 21,000), myoglobin (molecular weight 17,000) and cytochrome c (molecular weight 11,700).

Of the different detergent solutions used to solubilise the membrane preparations, 2.5% sodium dodecyl sulphate (SDS) was found to give the best recovery in the gels (over 90% of the radioactivity originally present in the sample). In more damaging conditions (4% SDS) this recovery was only 5%.

The gel staining pattern and the distribution of radioactivity indicate that all the ^{3}H-retinol present in the gel is bound to a single Coomassie-blue stained band. Typical results are reproduced in Fig. 2. The electrophoretic mobility of this protein band is higher than that of native human RBP and indicates a molecular weight of approximately 14,500. This band follows in the gel a minor Coomassie-blue staining band which has a molecular weight

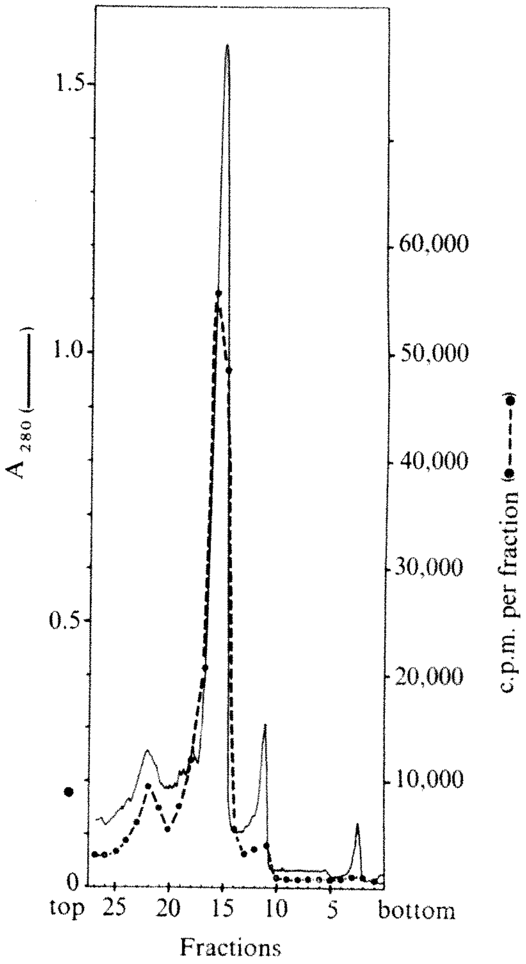

Fig. 1 Scanning and labelling profiles of homogenate of bovine PE preincubated with ^{2}H-retino-RBP and fractionated on a discontinuous sucrose gradient by centrifuging for 150 min at 27,000 r.p.m. in a SW 40 rotor with a L_2 Spinco ultracentrifuge. The following sucrose solutions were layered in the centrifuge tube from bottom to top: 44%, 40%, 36%, 33%, 15%. The gradient was scanned at 280 nm utilising a LKB pump and a Pye-Unicam SP 1700 spectrophotometer. Fractions of 0.5 ml were collected. 15μl aliquots of each fraction were tested for radioactivity in a Tricarb scintillation spectrometer (model 2425).

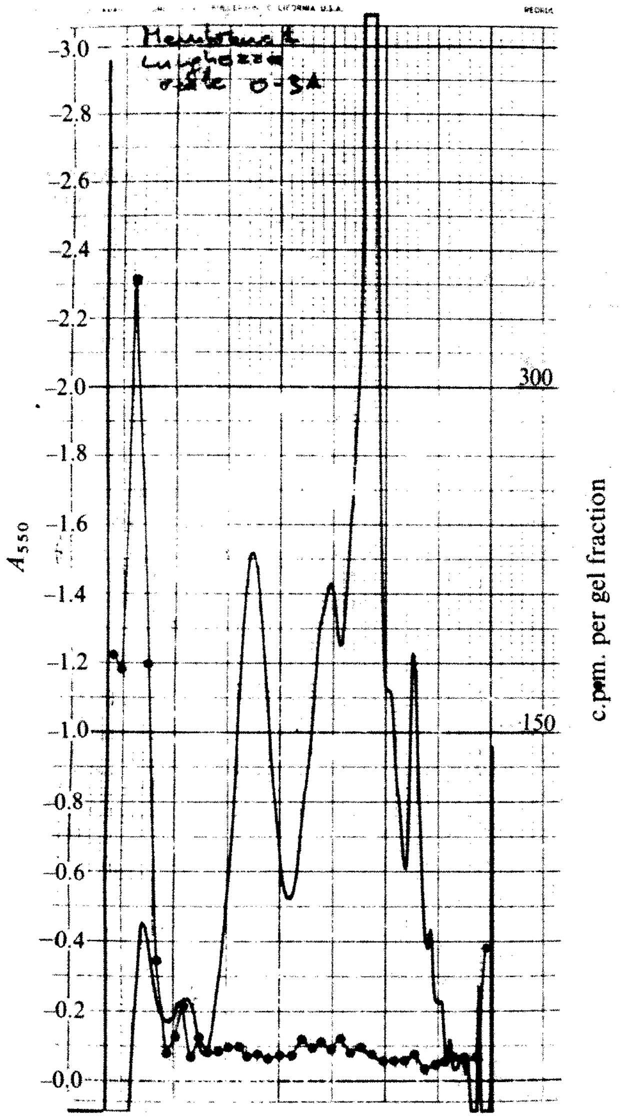

Fig. 2 Staining and labelling profiles of plasma membrane proteins from bovine PE preincubated with ^{3}H-retinol-RBP. Plasma membranes were dissolved overnight at room temperature with 2.5% SDS and 1% dithiothreitol in 0.3 M Tris-Cl$^-$ buffer (*p*H 8.9) and analysed for protein and radioactivity distribution by polyacrylamide SDS gel electrophoresis. The gels contained 7.5% acrylamide (stock solution 30% acrylamide, 0.8% *n-n'*-methylene-*bis*-acrylamide). The amount of protein applied to each gel was 50 µg. Gels were fixed and stained with Coomassie-blue. Scanning of the gels was performed at 550 nm. Duplicate unstained gel was sliced into 2.3 mm fractions, dissolved in H_2O_2 at 45 °C for 2 d, and resuspended in Toluene 70%, Omnifluor 0.4% metylcellosolve 30%. Radioactivity was determined by using a Tricarb scintillation spectrometer, with a counting error less than 1%.

of approximately 20,000 but which does not appear to contain appreciable radioactivity.

From the stained gel, after scanning, the protein band containing radioactivity was cut off. The gel slice was extracted three times with methanol and chloroform. The pool of the extracts was concentrated, applied on a thin layer of silica-gel F 254 and developed in the dark with a mixture of cyclohexane–ethanol 97/3 (ref. 11). Under ultraviolet light the chromatogram for reference retinol presented a principal spot with $R_f=0.51$ and two minor spots with $R_f=0$ and $R_f=0.95$ (oxidation products, probably the acid and the aldehyde). The sample zones corresponding to the three reference spots were scraped off, put in vials using 4% (w/v) Cab-O-Sil as gelling agent, and counted. Pure silica gel from the plate was scraped off as a blank. Radioactivity was present only in the principal spot ($R_f=0.51$); recovery of the gel radioactivity was 18%.

In four experiments isolated PE was incubated in the presence of iodinated human plasma RBP. Iodination of native RBP with ^{125}I sodium iodine and chloramine-T was performed as described by Heller[5]. After incubation with ^{125}I-RBP PE cells were treated as previously described. In none of the experiments could appreciable radioactivity be detected in the plasma membrane pellet at the end of the isolation procedure.

The gel staining pattern of plasma membranes of native PE (that is, not preincubated in the presence of RBP) is identical to that reproduced in Fig. 2 indicating that, under the experimental conditions used, no detectable change in the membrane protein composition was caused by the incubation with RBP.

Present results indicate that a protein able to bind retinol maybe extracted from the plasma membranes of PE incubated in the presence of exogenous RBP and is probably involved in the process of active retinol uptake by these cells. The molecular weight of this protein, calculated by SDS gel electrophoresis according to Weber and Osborn[12], is of the order of 14,500. This observation together with our inability to detect appreciable amounts of ^{125}I-RBP in the membrane preparation at the end of the isolation procedure suggests that the retinol-binding protein extracted from PE membranes is not the exogenous RBP present in the incubation solution. The same protein band was identified in SDS extracts of native PE membranes, which suggests that this protein is a normal constituent of this membrane. Nothing can be said at present about the possible relationship of this membrane protein with the low molecular weight retinol-binding proteins (molecular weight 17,000) recently demonstrated[13] in the cytosol fraction of PE.

Specific binding sites for oestrogen at the outer surfaces of isolated endometrial cells

OESTROGENS are more readily accumulated and retained in responsive cells than in cells that are not their targets[1]. Cytoplasmic macromolecules[2] which specifically interact with oestradiol and other steroid hormones seem to mediate transfer of the agonist to the nuclear chromatin, where the complex is believed to promote expression of the phenotypic effects[3–6]. It is generally assumed that the hormone diffuses passively to "cytoplasmic" receptors which determine the cellular specificity of response[7]. But some experiments indicate that steroid hormones interact with components of biological membranes and may enter their respective target cells by a membrane-mediated process[8-12] which is saturable and temperature-dependent[13-17]. We have investigated steroid-binding components associated with the plasma membranes of cells isolated from endometrium, liver and intestinal mucosa. Endometrial and liver cells show substantial binding to oestrogen immobilised by covalent linkage to an inert support, while intestinal cells have no such binding sites. The relative quantity of these steroid receptors at the outer surfaces of cells from diverse tissues corresponds well with the capacity of a given cell to accumulate and retain oestrogen.

Uterus, liver and intestine were excised from female rats that had been ovariectomised at 6 weeks old and maintained for 3 weeks in a low-steroid environment[16]. Epithelial cells were isolated from the mucosal surfaces of uterus and intestine by methods described before[18]. In brief, the procedures involved incubation with 20 mg of collagenase (Type I, Worthington) per 100 ml of Ca^{2+}-, Mg^{2+}-free Ringer, followed by restoration of divalent cations. Complete Ringer solution consisted of 136.9 mM NaCl, 2.7 mM KCl, 0.6 mM $CaCl_2$, 0.5 mM $MgCl_2$, buffered at *p*H 7.4 with 8.1 mM Na_2HPO_4 : 1.5 mM KH_2PO_4. Liver cells were isolated from excised tissues essentially by the method of Howard and Pesch[19] with 200 mg of collagenase per 100 ml of the above media. Cellular debris and damaged cells were removed from the cell suspensions as described before[12,18]. As a restorative procedure, the cells were incubated for 120 min in complete Ringer solution enriched with 0.1% (w/v) highly purified albumin (Pentex) and 1 mM sodium pyruvate before the start of experiments. Throughout these and all subsequent manipulations, at least 90% of all cells excluded the vital dye, Trypan blue, at a final concentration of 0.05% in Ringer solution during a 10-min incubation at 22 °C.

For determinations of total cellular uptake of free oestradiol, cells were diluted with fresh Ringer solution to a final concentration of 1×10^7 cells per ml. Incubations (5–60 min) were begun with the addition of 6, 7-^{3}H-oestradiol-17β (99 Ci mmol^{-1}, New England Nuclear; final concentration, 1×10^{-9} M) at 22 °C in oxygen. A 200-fold excess of unlabelled oestradiol-17β ($E_2\beta$) was added to paired samples for determination of displaceable or nonspecific binding[14]. Incubations were terminated by dilution with 4 volumes of ice-cold Ringer solution. The cells were then sedimented by centrifugation at 800 *g* (4 °C) for 5 min. The resulting cell pellets were washed three times by resuspending them in ice-cold Ringer solution and centrifuging as before. The washed pellets were sonicated at 0–4 °C, and the radioactivity in samples of the disrupted cells was determined by liquid scintillation spectrophotometry with 40–43% efficiency. Additional aliquots of the sonicate were analysed by the method of Hill and Whatley[20] for DNA.

To prepare oestrogen-derivatised supports for determinations of cell binding, fibres of transparent nylon monofilament (size 50, Penn Products), were strung into polyethylene rings (cut from S-6 stoppers, Mallinckrodt) as described by Edelman *et al.*[21]. The mounted fibres (8 mg nylon per ring), in individual Petri dishes (10×35 mm), were extracted to remove surface contaminants for successive 10-min periods with petroleum ether, carbon tetrachloride, 80% (v/v) methanol and water. The surface of the nylon was then partially hydrolysed with 3 N HCl for 30 min at 30 °C[22]. After thorough washing with water to arrest further hydrolysis, the fibres were activated with 12.5% (v/v) glutaraldehyde (grade I, Sigma) in 0.1 M phosphate buffer, *p*H 7.4, at 37 °C for 24 h (ref. 23). The reaction was terminated by exhaustive washing of the fibres with the buffer. The activated fibres were next in phosphate buffer and incubated for 18 h at 4 °C. Fibres placed in Petri dishes containing 5 ml of 2% (w/v) albumin were then washed with buffer to remove albumin that was not covalently bound to the activated nylon[23]. Samples of the combined washes were taken to determine protein by the method of Lowry *et al.*[24]. The introduction of albumin on the fibre was 0.12 mg per mg of nylon.

Oestradiol hemisuccinate was coupled to the albumin : nylon fibre with carbodiimide by procedures similar to those described by Sica *et al.*[25]. The protein-derivatised fibres were transferred to 20-ml beakers in which were placed 10 ml of 70% (v/v) aqueous dioxane containing 17β-oestradiol 17-hemisuccinate (272 μg per mg of albumin, Sigma). Two 50-mg portions of 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (Aldrich) were added (at 0 and 4 h). The samples were rocked gently for 18 h at 22 °C. The fibres were then washed at the same temperature successively with a total volume of 500 ml of dioxane (1 h), 5 l of 80% methanol (72 h), and 500 ml of water (15 min). The oestrogen-derivatised fibres were transferred to fresh Petri dishes, dried and stored *in vacuo* at 0–4 °C until use. The amount of covalently bound oestrogen was determined in three samples by incubation of derivatised fibres (0.36 mg albumin) with 2 ml of 0.5 M NaOH at 22 °C for 2 h. After stoichiometric neutralisation with HCl, the free oestradiol was

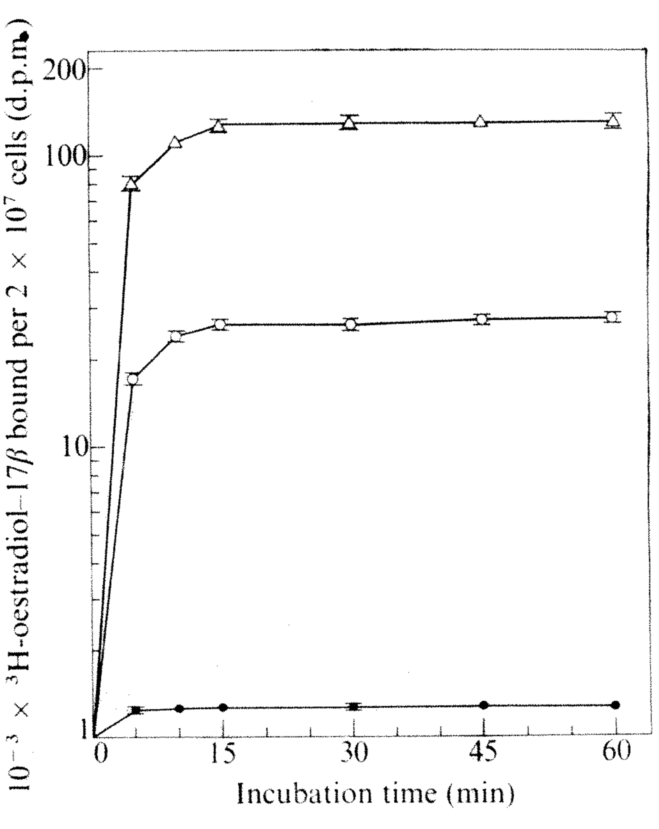

Fig. 1 Uptake of ^{3}H-oestradiol-17β by intact cells. Cells isolated from intestinal mucosa (●), liver (○) and endometrium (△) were incubated at 22 °C for 5–60 min with 1×10^{-9} M ^{3}H-$E_2\beta$ as described in the text. Only specific binding (defined as the difference in bound steroid between paired tubes, one of which contained a 200-fold excess of unlabelled $E_2\beta$ throughout the experiment) is shown. Specific binding of $E_2\beta$ by liver and endometrial cells (22 °C, 30 min) was not reduced significantly in the presence of the relatively inert oestradiol-17α at a concentration of 2×10^{-9} M ($P > 0.80$). Among liver and endometrial cells incubated at 4 °C for 30 min with 1×10^{-9} M ^{3}H-$E_2\beta$, specific oestrogen binding was reduced to 26% of that bound to paired cells maintained at 22 °C (both at $P < 0.01$, Student's *t* test). The extent of $E_2\beta$ binding is expressed relative to cell numbers, as derived from determinations of cellular DNA content (for example, 8.3, 10.6 and 9.3 μg of DNA per 10^6 cells of endometrium, liver and intestinal epithelium, respectively). Detailed analyses of specific oestrogen uptake, to be presented elsewhere, indicate that binding sites per endometrial, liver and intestinal mucosal cell average ~ 24,000, 3,400 and 50, respectively.

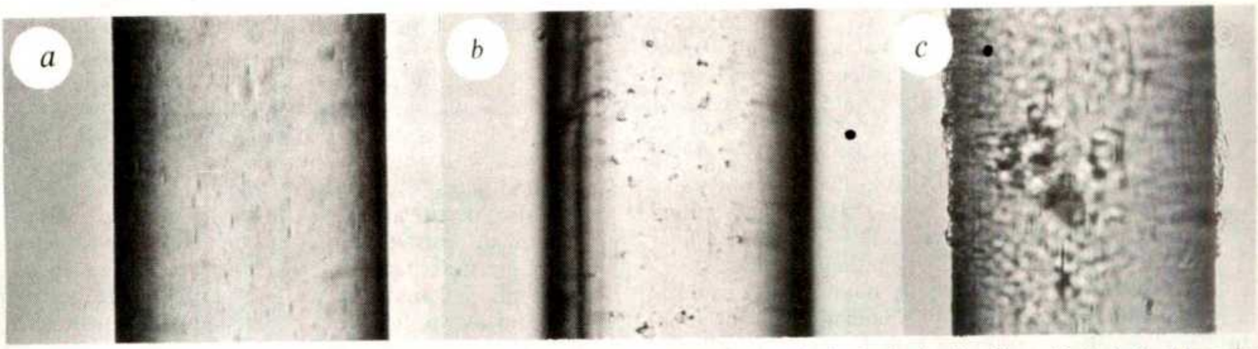

Fig. 2 Binding of isolated cells to oestrogen immobilised by covalent linkage to albumin-derivatised nylon fibres. Cells derived from intestinal mucosa (*a*), liver (*b*) and endometrium (*c*) were incubated with the derivatised fibres by addition of 1×10^7 cells per 4 ml of Ca^{2+}-, Mg^{2+}-free Ringer solution to a 10×35-mm Petri dish with the mounted fibres (8 mg of nylon per dish). The dishes were placed on a platform shaker (80 oscillations per min) at 22 °C for 30 min, after which unbound cells were separated by complete immersion of the dish successively in a series of three beakers, each containing 10 volumes of the incubation medium. The washed fibres with retained cells were then transferred to 4 ml of fresh incubation medium for photomicrography, using an immersion lens and Kodak Tri-X Panatomic film (ASA 400). Significant numbers of hormone-responsive cells (that is endometrial and liver cells) adhere to the fibres, whereas "nontarget" cells from intestine are poorly retained. No binding of any cells was observed when underivatised fibres or fibres coupled only to albumin were used (×250).

extracted with four equal volumes of diethyl ether (Mallinckrodt) that had been freshly saturated with double distilled water. The combined ether extracts were repeatedly backwashed with water, and evaporated at room temperature with a stream of nitrogen. Oestrogen was determined in the resultant residue by radioimmunoassay[26] (courtesy of Dr R. Swerdloff). The minimal substitution of oestradiol was 1 ng per mg of albumin.

Figure 1 shows the extent of uptake of 1×10^{-9} M ^3H-$E_2\beta$ by intact cells isolated from endometrium, liver and intestinal mucosa. The specific accumulation reported here represents the amount of radioactivity not displaced by the addition of a 200-fold excess of unlabelled $E_2\beta$. Among all cells incubated at 22 °C, accumulation of $E_2\beta$ was essentially maximal within 10–15 min, and there was no further increment in uptake of steroid for up to 60 min of incubation. As anticipated, endometrial cells retained the most $E_2\beta$ per cell. The moderate level of hormone uptake observed in liver cells is consistent with evidence for the presence of specific oestrogen receptors in rat liver[27,28]. The least retention was seen with epithelial cells from intestine, which is considered not to be a target tissue for oestrogen[29]. In addition, $E_2\beta$ binding to liver and endometrial cells maintained at 4 °C for 30 min was approximately four times less than that bound to corresponding cells incubated in the same conditions, but at 22 °C (Fig. 1).

To probe for steroid-binding sites at the external surfaces of cells derived from endometrium, liver and intestinal mucosa, isolated cells were incubated with the mounted 17β-oestradiol-17-hemisuccinyl: albumin: nylon fibres in the standardised conditions indicated in Fig. 2. Cells retained by the oestrogen-derivatised fibres after extensive washing were observed by microscopy. Significant numbers of hormone-responsive endometrial and liver cells were found to adhere to the steroid-derivatised fibres, but nontarget cells from intestine were essentially not retained (Fig. 2). Since there was no association of cells when unmodified nylon fibres or fibres derivatised only with albumin were used, the binding to oestrogen-derivatised fibres by target cells exclusively must be attributable to the presence of the steroid and the occurrence of specific recognition sites at the external surfaces of given cells.

A quantitative estimate of cell binding to the derivatised fibres was obtained as described in Fig. 3. Most fibre-bound cells could be displaced and recovered free and apparently intact by competitive inhibition of binding with excess $E_2\beta$, but not with oestradiol-17α($E_2\alpha$) added to the medium. Remaining cells were dislodged by brief exposure to hypotonic saline[21]. Among all cell types, the number of bound

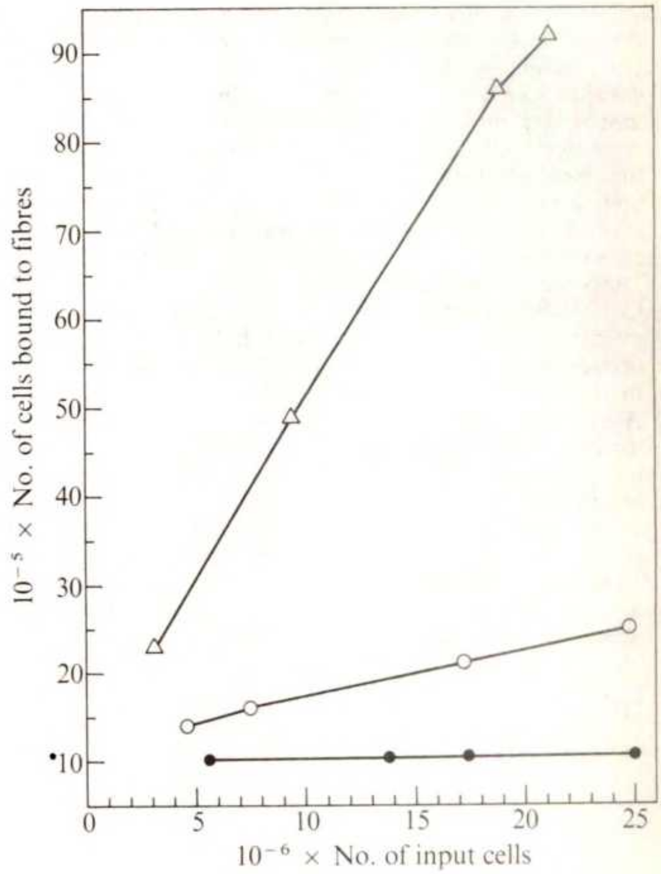

Fig. 3 Extent of cell binding to oestrogen immobilised on nylon fibres. Cells isolated from intestinal mucosa (●), liver (○) and endometrium (△) were incubated with the fibres by the addition of 3–25×10^6 cells per 4 ml of medium using standard conditions of mixing and shaking (Fig. 2). After removal of unbound cells, cells attached to the derivatised fibres were dislodged by incubation for 1 h in divalent cation-free Ringer solution containing 2×10^{-7} M $E_2\beta$, followed by 1 min of incubation in hypotonic (150 mosm) saline[25] with excess $E_2\beta$. ($E_2\beta$. ($E_2\alpha$ was ineffective in displacing cells from their association with fibres.) Cells recovered by these procedures were disrupted by sonication at 4 °C, and samples of the sonicate were taken for determination of cellular DNA contents. Cell numbers reported here were derived from measurements of DNA content per cell (Fig. 1). Each data point represents the mean of two or three independent experiments. The relation of the number of fibre-bound cells to total cells present in the incubation medium is defined by the slope, 0.003 for intestinal cells ($r = 0.98$), 0.054 for liver cells ($r = 0.99$), and 0.386 for endometrial cells ($r = 0.99$).

cells was a linear function of the cell concentration over a wide range (Fig. 3). This result suggests that, in the conditions specified, binding is proportional to the number of input cells; the binding of one cell is independent of that of others, and the fibre surface is not saturated with cells. As in analyses of total cellular uptake of $E_2\beta$ (Fig. 1), the capacity of endometrial cells to bind oestrogen coupled to a fibre surface surpassed that of cells from liver and intestine. The percentage of total input cells that become bound averaged 40±1 (9) for endometrial cells, 7±1 (8) for liver cells, and 0.3±0.1 (8) for intestinal epithelial cells.

The number of endometrial cells bound to derivatised fibres was significantly reduced by incubation at low temperature and also by exposure of cells to free $E_2\beta$ followed by three washes at 400*g*, before incubation of the cells with fibres in the standard conditions (Table 1). Binding of oestrogen at the outer surfaces of cells incubated at 4 °C was four times less than that to paired cells maintained at 22 °C. Association of $E_2\beta$-pretreated cells with derivatised fibres (at 22 °C) amounted to 42% of that of corresponding endometrial cells exposed only to hormone vehicle, ethanol, at a final concentration of 0.02% ($P<0.01$). In contrast, prior incubation of these cells with $E_2\alpha$ elicited no significant reduction in the subsequent binding of washed cells to the test fibres compared with that of control cells ($P>0.90$).

These studies provide direct evidence that receptor components specific for oestradiol-17β, but not for the 17α-isomer, are present at the external surfaces of oestrogen-responsive cells. These results seem to be in conflict with the assumption that steroid hormones enter all cells by nonspecific, free diffusion[6,30]. Several investigators, however, have noted marked saturability and temperature-dependence of steroid hormone entry, which cannot be attributed to the function of cytoplasmic receptors[13-17]. Our studies are consistent with these observations. Moreover, the decline in oestrogen accumulation by target cells at reduced temperature may be attributable to a reduction in the availability of surface receptors for the hormone. Alterations in the physical state and orientation of various membrane macromolecules may contribute to the reduced interaction of oestrogen with surface binding components at low temperatures[13,31-33].

The number of surface sites available for binding to oestrogen-derivatised fibres is markedly diminished in endometrial cells after exposure to oestradiol-17β, but not after treatment with the relatively inactive 17α-isomer. This may be attributable to masking of the external sites by bound oestrogen or to a hormone-induced change in the location or orientation of the oestrogen-binding components. Other studies have shown that target-selective uptake of specific antigens is associated with localised disordering of membrane structure and subsequent internalisation, presumably of those regions of the surface membrane equipped with, or immediately adjacent to, specific recognition sites[34-36]. A corresponding sequence of events may also occur at the surfaces of endometrial cells in response to oestrogen, as is evident from reports of altered membrane functions[12,37,38] and micropinocytotic vacuolation of the plasmalemma[38] after brief exposure to oestrogen.

Table 1 Effect of temperature and prior treatment with oestrogens on the binding of isolated endometrial cells to oestrogen immobilised by covalent linkage to albumin-derivatised nylon fibres.

Incubation temperature (°C)	Treatment before incubation	No. of fibre-bound endometrial cells number of input cells (%)
22	None	40±1 (3)
4	None	10±1 (3)*
22	Oestradiol-17α ($1+10^{-8}$M, 1 h)	39±2 (3)
22	Oestradiol-17β ($1+10^{-8}$M, 1 h)	17±2 (3)†

The extent of endometrial cell binding to oestrogen-derivatised fibres at 22 °C or 4 °C was determined as described in Figs 2 and 3. The number of cells added to each incubation vessel, the input cells, averaged 2×10^7 (≃166 μg DNA). In some experiments, cells were treated for 1 h with 1×10^{-8} M $E_2\beta$ or $E_2\alpha$ and then washed three times in steroid-free medium at 400*g* (5 min) before exposure to the derivatised fibres in the standardised conditions. All data are presented as mean±s.e.m. with the number of determinations in parentheses.

* Value significantly different from appropriate control at $P < 0.001$.

† Value significantly different from appropriate control at $P < 0.01$ (Student's *t* test).

In contrast to numerous reports devoted to the identification of membrane-associated receptors for polypeptide hormones[39,40], membrane-binding sites with specificities for steroid hormones have scarcely been investigated. Our work provides direct proof that such sites exist at the surface membrane of cells responsive to oestrogen. But the nature and origin of these binding components and the manner in which they may contribute to the recognition and mediation of entry of oestrogenic hormones remain to be determined.

This investigation was aided by grants from the US PHS and the NSF We thank B. J. Seeler, M. B. Nazareno and K. A. Thompson for technical assistance.

Abnormal myelination in transplanted Trembler mouse Schwann cells

AXON and Schwann cell interdependence has received increasing attention in recent years[1,2]. In normal nerves, axons influence Schwann cell proliferation[3,4] and myelin formation[5-8]. These interactions may also be important in peripheral nerve disorders. Indeed, it has been suggested that in certain neuropathies, it is an axonal abnormality which is responsible for the failure of Schwann cells to maintain normal myelin[9,10]. An experimental approach to this question has become possible with the demonstration that, in nerve grafts from normal animals, Schwann cells which originate in donor nerves ensheath and myelinate axons arising from nerve cells in the host[6,8,11]. This demonstration of the feasibility of *in vivo* combinations of Schwann cells and axons, each originating from different animals, prompted the present experiments in which axons and Schwann cells from normal and abnormal mice were combined in sciatic nerve grafts. For the present study, abnormal nerves were obtained from Trembler mice (Tr)[12]. These mutants have a dominantly inherited neuropathy characterised by the presence of abnormally thin myelin sheaths and slow conduction in the peripheral nerves[13], changes which have been considered to resemble those of human hypertrophic neuropathies[14].

To define further the abnormality in Tr neuropathy, sciatic nerves and spinal roots from six affected mice and five control C57BL/6J mice aged 14 d to 7 month were examined by phase and electron microscopy[6,15]. In normal nerves, most axons greater than 1 μm in diameter were surrounded by Schwann cells containing a myelin sheath; in Tr nerves, between 30 and 70% of Schwann cells ensheathing fibres of this size lacked myelin completely and the remainder had thin myelin sheaths (hypomyelination). Complete counts of axons and Schwann cell nuclei were obtained from electron microscope montages of whole transverse sections taken from the mid-portion of the 10 to 15 mm long L4 ventral roots of four adult control and Tr mice[15]. The average number (±s.e.) of axons in controls (914±17) and Tr mice (856±55) was similar. Schwann cell nuclei were of equal size in both groups of animals, but there was a 10-fold increase in the number of Schwann cell nuclei in L4 ventral roots of Tr mice compared with controls (266±24 and 22±4 respectively). Although this hypercellularity in Tr nerves could be due to a chronic demyelinating process[16,17], it may also be secondary to a developmental failure of myelination: the length of Schwann cell territories in teased fibres of Tr mice of all ages studied has been found to be less than normal (unpublished work). Presumably because of the interdependence of myelin thickness and the length of Schwann cell territories[18], both the radial and the longitudinal extension of these cells may be similarly deficient in Tr mice nerves; as a result, axonal ensheathment in fibres which are hypomyelinated or lack myelin must only be possible through a neonatal increase in Schwann cell number. Finally, there were no inflammatory cells or macrophages in Tr sciatic nerves or roots, and neither myelin debris, an indicator of active demyelination, nor concentrically arranged Schwann cell processes (onion bulbs)[16,17] were prominent features in the Tr nerves we have examined.

Because these quantitative and morphological findings indicated Schwann cell abnormalities and no axonal loss in Tr neuropathy, interactions between axons and Schwann cells were investigated in sciatic nerve grafts. In 26 mice, approximately 6 week old, a 5 mm segment of the sciatic nerve was removed from a donor mouse and immediately grafted between the cut ends of recipient sciatic nerves at the mid thigh level. The graft was secured to host nerve

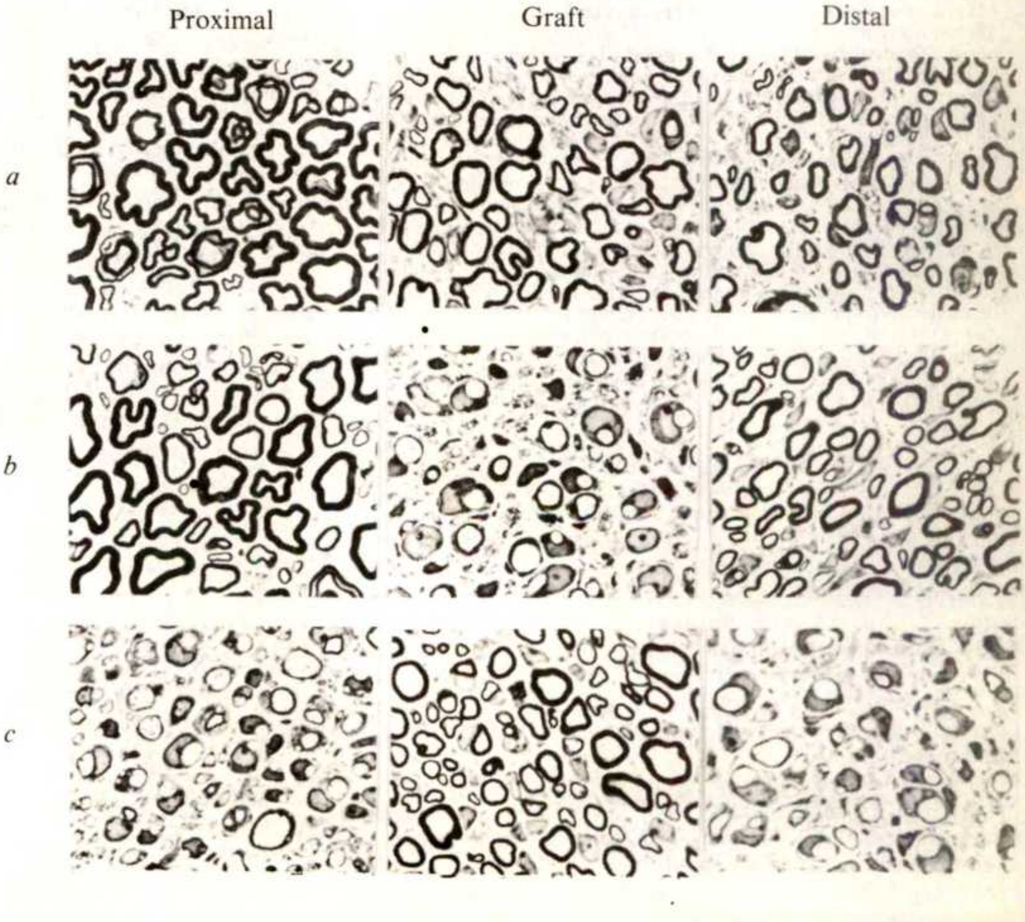

Fig. 1 Phase micrographs of sciatic nerves at three different cross-sectional levels 2 months after grafting. Sections were taken approximately 3 mm from the graft (proximal stump), the mid-portion of the graft, and 3 mm distal to the graft (distal stump). *a*, Normal-to-normal grafts. Grafted segments and distal stumps contain numerous regenerated myelinated fibres which closely resemble those in the proximal stump. *b*, Trembler-to-normal grafts. Proximal and distal stumps (recipient nerves) appear normal, while fibres within the graft either lack myelin or are hypomyelinated. *c*, Normal-to-Trembler grafts. Proximal and distal stumps of host nerves show many fibres with little or no myelin but the morphology of fibres in the graft resembles that of normal regenerated nerves.

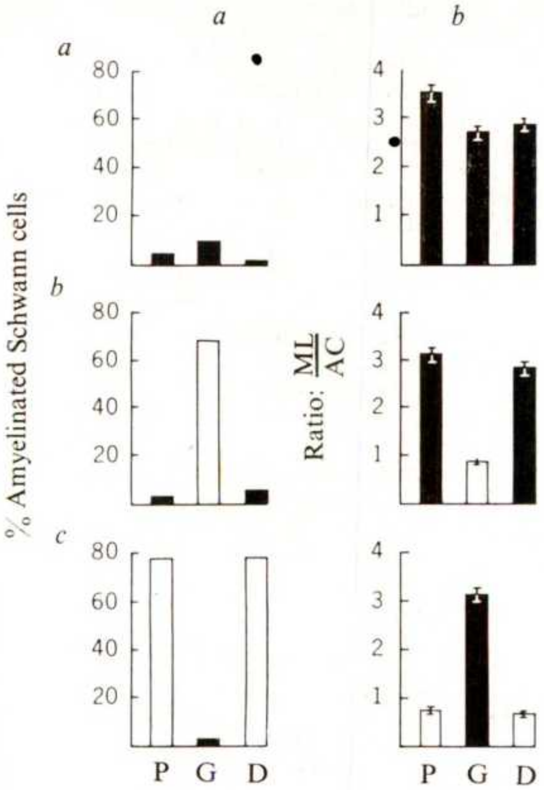

Fig. 2 Proportions of nerve fibres with Schwann cells containing no myelin (*a*) and ratios of the number of myelin lamellae to axonal circumference (ML/AC) in myelinated fibres (*b*) from cross sections of proximal (P), graft (G) and distal (D) segments from sciatic nerves 2 months after grafting. Solid bars represent data from normal nerve segments; open bars symbolise values in segments from Trembler nerves. The percentage of fibres with no myelin, calculated at each level for an average of 230 axons greater than 1 μm in diameter, is expressed as mean ± s.e.m. The ML/AC was measured in 100 fibres at each level from electron micrographs at a final magnification of × 9,100. In N–N–N nerves, fewer than 10% of regenerated fibres at level G and D lack myelin, and ML/AC ratios are normal[20]. In normal regenerating nerves, fibres with no myelin probably represent premyelinated fibres as well as nodes of Ranvier, increased in number because of the shortening of Schwann cell territories along regenerated fibres[21]. The proportions of fibres with Schwann cells that contain no myelin and the MC/AC ratios for the proximal and distal segments are similar for N–T–N and N–N–N nerves. In the grafted segments of N–T–N nerves, however, the proportion of fibres with no myelin is increased sevenfold and ML/AC ratios are only one-third those of normal grafts, indicating that myelin sheaths remain inappropriately thin in relation to axonal diameters (hypomyelination). These findings for N–T–N experiments are reversed in the T–N–T experiments: non-myelin containing Schwann cell percentages and ML/AC ratios are normal in the graft but values in the regenerated distal stump resemble those of the Tr recipient proximal stump.

stumps by 10-0 nylon sutures placed through the epineurium. Three different combinations of nerves were prepared:

- Normal-to-normal nerve grafts (N–N–N). Nerves from normal C57BL/6J mice were grafted into sciatic nerves of 14 non-littermate animals of the same strain. Thus, in this group of mice, normal axons regenerating from the proximal stump of the host should associate with normal Schwann cells in the graft and eventually grow into the distal nerve stump.
- Trembler-to-normal nerve grafts (N–T–N). Segments of nerve from Tr mice were grafted between the stumps of sciatic nerves in six normal C57BL/6J mice. In this group, axons from normal nerves should regenerate across a graft containing Schwann cells from abnormal Tr nerves.
- Normal-to-Trembler nerve grafts (T–N–T). Segments from C57BL/6J mice were grafted into six Tr sciatic nerves. In these animals, Schwann cells from a normal graft should ensheath Tr mouse axons.

To prevent graft rejection, anti-lymphocytic serum (prepared by injecting rabbits with a suspension of 10^9 living thymocytes from C57BL/6J mice[19]) was injected subcutaneously in doses of 0.5 ml twice weekly, beginning on the day of grafting. Two, three and four months after grafting, animals were killed by systemic perfusion of 3% glutaralderhyde and the nerves processed according to standard techniques for quantitative ultrastructural studies[6]. In all experimental groups, no grafts were rejected and axons from the proximal stumps, whether from normal or Tr mice, successfully bridged the graft.

In all experiments, as regenerating axons grew into the grafts, the morphological features of the donor nerve were fully reproduced by the grafted Schwann cells (Figs 1 and 2). The boundaries between normal and abnormal nerve segments were well delineated in these experiments. In N–T–N regenerated nerves, the widespread hypomyelination and absence of myelin, which are the hallmarks of the Tr neuropathy, were duplicated in the grafts and contrasted abruptly with the normal myelin in the recipient nerve stumps. Because Schwann cells proliferate intensely soon after grafting[6,8,11], these findings demonstrate that the manifestations of the gene responsible for the Tr neuropathy are fully expressed by the transplanted Schwann cells and their daughter cells. There was no indication from the T–N–T experiments that axonally mediated or general systemic factors were involved in the pathogenesis of the neuropathy; the Tr abnormality was not induced in normal Schwann cells transplanted into Tr mice.

These experiments have established the feasibility of *in vivo* combinations of axons and Schwann cells from normal and pathological nerves. They have also proved unequivocally that the Tr neuropathy is due to a primary disorder of Schwann cells. Because conditions in the host animal might be expected to modify the behaviour of transplanted Schwann cells, the technique used in the present study should be helpful in elucidating other pathogenic mechanisms; for example, it should be possible to show whether axons or general metabolic factors are responsible for myelin abnormalities in other neuropathies. Observations in these experiments with Tr mice should also be of value in understanding the pathogenesis of the hypomyelination observed in other neuropathies, both in man[22,23] and experimental animals[24].

Finally, our findings provide further proof that Schwann cells in grafts from distal stumps of nerves regenerating in continuity originate from Schwann cells and not by migration from the proximal stumps[6,8,11].

Anti-lymphocytic serum was provided by Dr P. Kongshavn, Department of Physiology, McGill University.

Spontaneous and evoked potentials from dissociated epithelial cells of *Hydra*

ALTHOUGH intracellular recording from excitable cells has a thirty-year history, such recording from coelenterate tissue has only recently been achieved[1–4]. Mechanical dissociation of previously separated endodermal and ectodermal epithelial layers of *Hydra* produces a preparation permitting intracellular recording from identifiable classes of cells (Fig. 1). Elicited and spontaneous potentials occur in the cells of both epithelial layers. We have recorded small rhythmically occurring pulses from endodermal cells with positive resting potentials; large spikes from ectodermal cells with negative resting potentials, and regularly occurring membrane oscillations from both types of cells.

Cells could be held for up to 3 h, but we generally withdrew the electrode after 20–45 min. Some records only lasted 10 min (see legend of Fig. 2). Cell types were consistently recognisable (Fig. 1) and pulses were obtained from medium-sized endodermal epithelial cells (20–35 μm), having few vacuoles or enclosures; from smaller endothermal interstitial cells (10–15 μm), and from large (>30 μm) ectodermal epithelial cells. Of the cells penetrated only about 5% produced pulses.

Resting potentials in all solutions were positive for almost all endodermal epithelial and interstitial cells (Fig. 2). These ranged from +3 mV to +25 mV, with the majority between +7 mV and +12 mV. Ectodermal cells had negative resting potentials of −2 mV to −25 mV. The five nerve cells penetrated gave resting potentials of −5 mV to −7 mV. During the usual 4–6 h recording session, all intact cells had resting potentials. Whenever successive penetrations yielded no resting potentials, the cells were judged dead and so discarded.

To compare our resting potentials with those in intact animals, intracellular recordings from endodermal and ectodermal cells of intact *Hydra* were undertaken. Animals were immobilised by prior colchicine treatment[9,10] and turned inside out[11] for endodermal cell recordings. Recordings were done in *Hydra* culture solution[12]; endodermal resting potentials ranged between +15 mV and +20 mV (seven cells); ectodermal resting potentials between −2 mV and −8 mV (eight cells).

Resting potentials of dissociated endodermal cells could be driven to negative values by increasing the sodium concentration above 18 mM. However, the cells produced numerous blebs (presumably a result of osmotic stress) and died within an hour or so. Varying the KCl concentration from 0.2 to 3 mM produced no apparent change in resting potentials; but raising the molarity above 3 mM KCl resulted in rapid cell death.

We have tentatively identified three categories of electrical activity: Group 1 pulses, reminiscent of typical junction potentials and of epithelial pulses in *Nanomia*[1]; Group 2 activity representing apparent membrane oscillations, and Group 3 potentials similar to typical action potentials and to epithelial potentials in *Hippopodius*[4]. The most striking characteristics in all three categories is the variability of the pulses, both in amplitude and time course, even within a particular sequence of pulses in the same cell.

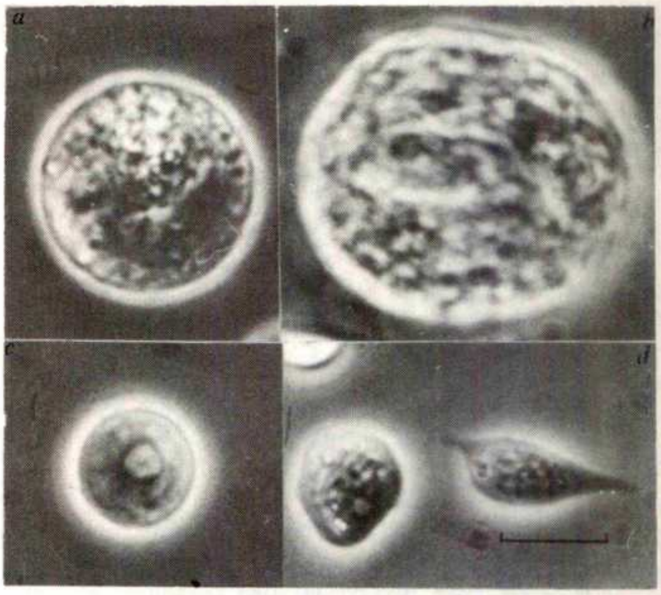

Fig. 1 Dissociated cells. *a*, Endodermal epithelial cell. *b*, Ectodermal epithelial cell containing a glutinant. *c*, Interstitial cell. *d*, Bipolar nerve cell and an interstitial cell. Scales indicate 10 µm. Preparations of dissociated cells from either or both epithelia of *Hydra attenuata* Pall. are made using methods modified from those of Papenfuss and Bodenham[5] and Gierer *et al.*[6] Endodermal epithelio-muscular cells are selectively collected by transecting whole animals at the peduncle, discarding the digestive-cell-bearing upper portions and pipetting the endodermal cells free from the remaining peduncle. Ectodermal cells are gathered by stripping the ectoderm free of endodermal cells in this way and then dissociating the remaining ectodermal shell by gentle pipetting in a centrifuge tube in the recording solution. After pipetting, the cells are filtered through a No. 63 Nitex cloth for additional dissociation and debris removal. Cells are collected by centrifugation for 5 s at top speed, followed by 3 s at medium speed in a clinicial centrifuge. They are then pipetted on to a collagen-covered recording dish on the stage of a Zeiss phase contrast inverted microscope and maintained at a temperature of 20 °C by means of a cooling unit in the microscope stage. Preparations were viewed under phase contrast optics (346×) during recording and both the impaled cell and the recording electrode remained visible throughout.

Group 1 potentials were recorded from single apparently isolated endodermal epithelial and interstitial cells and from cells in cell aggregates (Fig. 2). They often occurred as regular, rhythmic membrane depolarisations having relatively fast rise times (150 ms–2000 ms) and long decay periods (Time constants ranged between 500 ms and 2–4 s.) Amplitudes of the longer lasting pulses were between +2 mV and +5 mV (Fig. 2*a*); those with faster time constants between +0.3 mV and +0.6 mV (Fig. 2*b*).

The larger rhythmic pulses occurred at an average rate of 2 min^{-1} (1.74±0.21 (s.e.) for six cells) (Fig. 2*a*). The smaller pulses often occurred sporadically. They are perhaps best construed as miniature junctional potentials, since both negative-going and positive-going potentials of similar amplitudes and time courses were recorded (Fig. 2*b*).

Other pulses, similar in shape, time course and amplitude occurred as brief responses to stimuli given through the

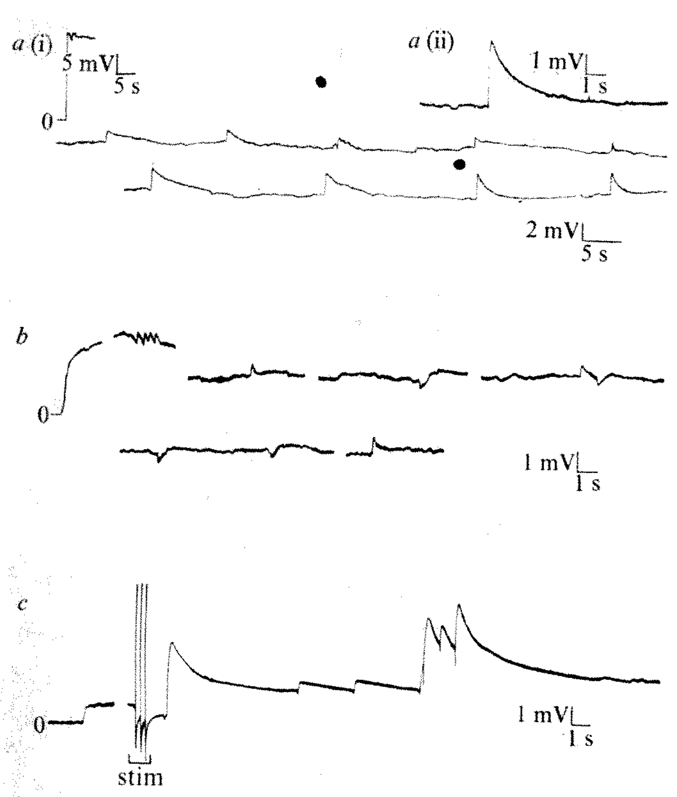

Fig. 2 Group 1 potentials from endodermal cells. Resting potentials are given at the left. Scales at right refer to all preceding pulses. Wave forms in this and all subsequent figures were traced with a pentograph from DC oscillograph records. In *a*(i) spontaneous pulses occur in an isolated cell at a regular rate of about 2 min^{-1}. *a*(ii) is the penultimate pulse enlarged. *b*, Small sporadically occurring spontaneous pulses from an isolated epithelial cell. Both positive and negative-going potentials continued on for 8 min before the electrode was withdrawn. *c*, Positive potentials elicited by a series of stimuli through the recording electrode in an epithelial cell in an aggregate of three cells. The pulses sum or facilitate and culminate finally in a larger, somewhat faster potential. Recordings were made with conventional 3 M KCl filled glass pipettes held by a pair of Jena micromanipulators. Potentials were led to an FET preamplifier with stimulating bridge and simultaneously monitored on a Haer Audio Analyser, a 5103N Tektronix storage oscilloscope and a 7402A Hewlett Packard chart recorder with d.c. amplifiers. Photographs of both cells and oscilloscope traces were taken with Polaroid cameras. A number of solutions were tried as recording media. In different solutions, the salt and sugar concentrations were varied as follows: NaCl from 10 to 15 mM, KCl from 0.2 to 2 mM, $CaCl_2$ from 5 to 8 mM, $MgCl_2$ from 0 to 0.3 mM, $NaHCO_3$ from 0 to 3 mM, EDTA from 0 to 1.4 mM, sugar from 0 to 25 mM. Group 1 recordings were obtained only in sugar-free solutions. Group 2 and 3 recordings in both sugar-containing and sugar-free solutions. All solutions were adjusted to a *p*H of 6.8 to 7.2 and had an osmolarity of between 60 and 70 mosM, the range of the osmotic concentration of the *Hydra* gut[7,8]. A solution was judged usable if the cells remained alive in it for 4 h, if the average value of resting potentials remained unchanged for 2 h and if the cells maintained their tonicity for 4 h. Although cells in sugar-containing solutions met the above criteria, they nevertheless eventually swelled and burst even when no glucose was present.

recording electrode. Those in Fig. 2*c* apparently sum or facilitate. They may indeed have resulted from antidromic stimulation to a nerve impinging on the cell.

Whether any of these decrementing pulses are endogenous or a result of nerve activity is not clear, although many were recorded from cells appearing to be nerve free. We may speculate, however, that since the frequency of the regular pulses falls within the range of the extracellularly recorded endodermal rhythmic potentials[11,13,14] of Passano and McCullough, they are associated with that pacemaker system.

● Group 2 potentials. A series of wave-like membrane oscillations were frequently encountered in endodermal epithelial cells and in some ectodermal cels (Figs 3 and 4).

In endodermal preparations, these were often preceded or accompanied by rapid negative-going potentials, occurring either spontaneously or in response to stimuli given through the recording electrode. The negative transients varied from −0.2 mV to −2 mV and usually disappeared after a while. In one case (Fig. 3*b*) they continued to occur in unison with their concomitant waves for some time; both finally stopping spontaneously. Their significance is not known, although in one recording there was an increase in wave frequency after a succession of these spikes.

These wave-like oscillations may represent a series of junctional potentials as described for other systems. In one preparation (Fig. 3) which had been allowed to dark adapt for 10 min and which was then suddenly illuminated through the condenser, the frequency of waves increased from a rate of 32 min^{-1} in the half minute before the light stimulus to 52 min^{-1} in the half-minute after the shock. Since the recording dish was on a microscope cooling stage, and the response to sudden illumination instantaneous, it it unlikely that this was actually a heat response. An increase in pulse rate similarly occurs in the extracellularly recorded rhythmic potential system when the bases of intact *Hydra* are stimulated with light[14]. It is quite possible, therefore, that this response may in fact be due to nerve activity.

Alternatively these oscillations may be a function of the membrane itself, since they can occur when spikes from a previously spiking ectodermal cell fail; the oscillations apparently replacing the spikes (Fig. 4). Waves in ectodermal cells also seem capable of developing into spikes (see below).

● Group 3 potentials were large, rapid spikes of +35 mV to +200 mV which could occur individually or in bursts (Fig. 4*a*). These arose spontaneously from cells, approximately 1.5 times the size of medium epithelial cells, which we classified as ectodermal epithelial cells (Fig. 1*b*).

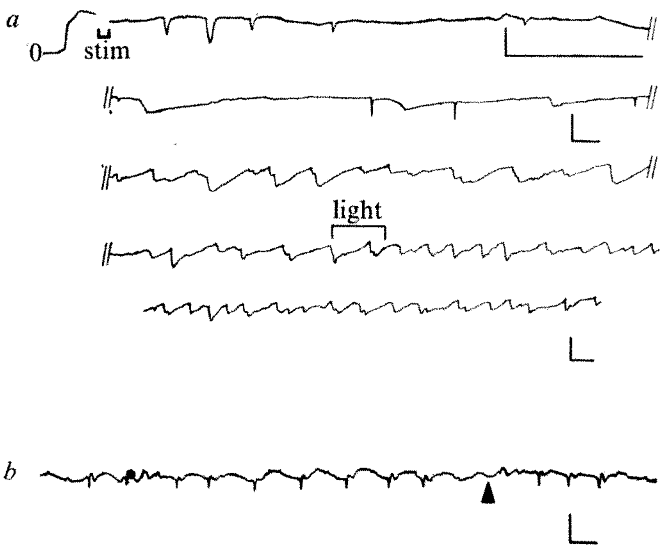

Fig. 3 Group 2 potentials from endodermal cells. Resting potential is on the left. Scales at right refer to preceding pulses (vertical axis equals 1 mV, horizontal axis equals 1 s). *a*, Rapid negative-going pulses elicited by stimuli through the recording electrode, followed by spontaneous oscillations of the membrane which increased in frequency after the first 5 min of recording and then slowed down again. A light shock given 53 min after penetration causes an increase in the oscillatory frequency in the same cell. Deletions from the record greater than 10 min are indicated by slashes. The absence of a slash indicates that the record is continuous. *b*, Spontaneous negative potentials accompanying membrane oscillations in another isolated epithelial cell. Arrow indicates an instance where the wave and spike occurred out of phase.

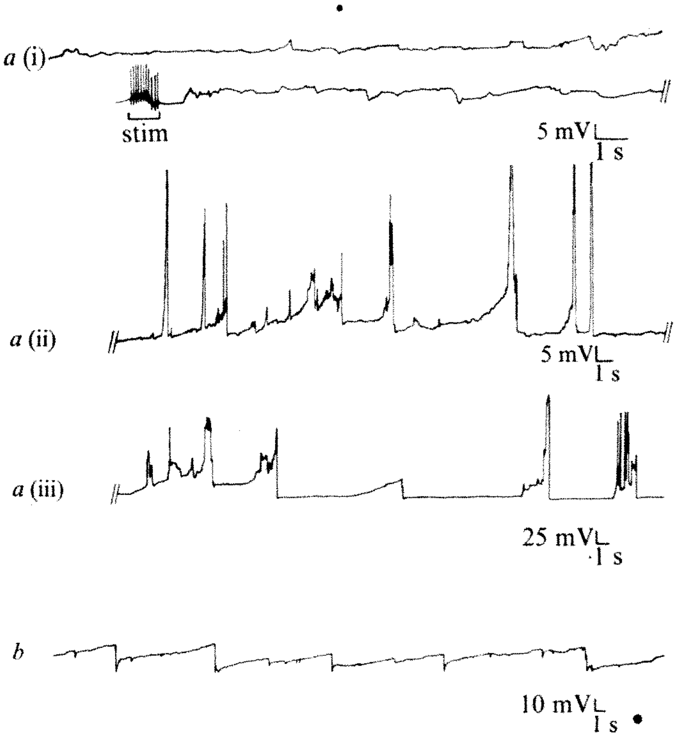

Fig. 4 Group 3 potentials from ectodermal cells having negative resting potentials. *a*(i), Spontaneously occurring membrane oscillations which increase in regularity in response to stimuli through the recording electrode. *a*(ii), *a*(iii), Large spikes occurring singly or in bursts in the same cell. In *a*(iii) the membrane does not always reach threshold. Deletions from the record greater than 8 min are indicated by slashes. The absence of a slash indicates that the record in continuous. *b*, Oscillations of the membrane potential recorded from a cell in an aggregate, which have replaced previously occurring spikes after 2.5 h of spontaneous spiking activity.

The spikes usually arose from gradual depolarisations of the mebrane and often had small after-hyperpolarisations. They frequently displayed a distinct rhythmicity (Fig. 4*a*(ii) and *a*(iii)).

As before, these too varied greatly in amplitude and time course. (Durations ranged between 300 ms and 900 ms.) This was so even for a series of potentials in the same burst. Irregularly shaped action potentials of various amplitudes are reported for other systems[15,16], as well as for coelenterates[2].

In one case, spikes arose from successive membrane oscillations which increased in frequency upon stimulation through the recording electrode. These grew into +15 mV depolarisations carrying spikes at their crests; they later became huge individual potentials greater than +200 mV. In another, Fig. 4*b*) the spikes were replaced after 2.5 h by rhythmic oscillatory waves having small negative-going pulses interspersed among them. (These were perhaps thus inhibitory junctional potentials.) The oscillations were reminiscent of those recorded from endodermal cells (Fig. 3).

Here too, we are not certain whether these pulses are endogenous or the result of nerve activity. But since the membrane potential itself often seemed to become unstable, exhibiting wave-like spontaneous depolarisations comparable to those known for vertebrate smooth muscle[17], it is conceivable that even if this activity were initially induced by nerves, once the cell had become active, it could continue to produce spikes endogenously. A relationship of these spikes to the extracellularly defined contraction burst system[18] is possible, but remains to be investigated.

In summary, then, although it is too early to classify these potentials with certainty, or to assign them to specific cell types, or to say whether they are endogenously produced by the cells from which they are recorded, it is nonetheless possible to offer tentative suggestions. We would like to propose that, on the basis of their distinct regularity, the rhythmically occurring Group 1 pulses are either junctional potentials which induce the endodermally conducted rhythmic potentials[13], or themselves underlie these potentials and that the oscillatory Group 2 membrane fluctuations may be a property common to both sorts of excitable epithelial cells. This suggests that *Hydra* epithelial cells possess properties typical of spontaneously active cells whose membranes are capable of prolonged periods of intermittent endogenous depolarisations[17,19]; even if these depolarisations are initially induced by nerve activity.

This work was supported by an NSF grant. R. P. McCormick executed the text figures. Thanks are expressed for the anonymous donation to purchase the microscope camera and to R. B. Hill and A. N. Spencer for suggestions. We thank L. M. Passano for comments.

Response of cricothyroid muscles to frequency-modulated sounds in FM bats, *Myotis lucifugus*

BATS of the species *Myotis lucifugus* use short frequency-modulated (FM) ultrasonic pulses for echolocation. The duration, repetition rate and frequency of these pulses vary from time to time depending upon whether the animal is searching for, approaching or actually capturing its prey. The bat emits 2–5 ms pulses at a rate of 10–20 s^{-1} with the frequency of each pulse sweeping approximately one octave from 80 to 40 kHz during the searching and cruising flight; it produces 0.3–1.0 ms pulses at a rate of 150–250 s^{-1} with a downward-sweep FM from 40–20 kHz immediately before avoidance of obstacles or capture of a prey[1,2]. Among the laryngeal muscles of the bat, the cricothyroid muscle (CTM) in particular, is highly developed and is essential in producing the intense orientation pulses[1,3]. The CTM not only discharges action potentials before the vocalisation[3–5], but also during the acoustic stimulus[6,7]. The latter phenomenon is called the acoustic laryngeal muscle reflex and might serve as a negative feedback to stabilise the performance of the vocalisation system[6]. Comparative studies of the properties of the middle ear and laryngeal muscles revealed significant differences between these two muscles (refs 6 and 7 and P.H.-S.J., J.O., and N. Suga, in preparation). We found that CTM fibres were more sensitive to 4 ms FM signals sweeping downward with a range of 10 or 20 kHz across their best frequencies (BFs) than to pure tones.

Seven *M. lucifugus* were anaesthetised with ether for surgery. The exposed dorsal surface of the skull of a bat was mounted with the flat head of a 1.8 cm long nail with glue and dental cement and the animal was placed ventral side up in a body-sized box made of wire mesh. This box was suspended with rubber bands at its four corners so that it absorbed the body movement from the bat. The head of the animal was immobilised by fixing the shank of the nail into a metal rod with a set screw. The laryngeal muscle was then exposed. After the animals had recovered from the anaesthesia, the action potentials of single CTM fibres were recorded with sharpened and coated tungsten wires from the conscious animals and were displayed on the screen of an oscilloscope. An indifferent electrode of silver wire was placed on the nearby subcutaneous tissue. The electronic instruments used to generate acoustic stimuli were basically the same as described elsewhere[8,9]. Briefly, tone pulses with duration of 4 ms and 0.5 ms rise–decay time were delivered at a rate of 1.5 s^{-1} from a condenser loudspeaker placed 75 cm in front of the animal. The loudspeaker was calibrated with a Brüel and Kjaer ¼ inch microphone placed at the bat's ears and its output was expressed in dB SPL referred to 2×10^{-4} dyne/cm^2 root mean square. Frequency-modulated signals sweeping at a range of 5, 10, 20 and 30 kHz respectively during the 4 ms duration were generated from a VCG Wavetek (model 186) driven by a sawtooth generator. The sweep range of FM pulses were carefully adjusted so that their centre frequencies were always at the BF of each investigated fibre. The discharge pattern of 52 CTM fibres studied were always tonic-on responding, that is they discharged many action potentials during the stimulus. The shortest latency of this acoustic cricothyroid muscle (CTM) reflex was 6.2 ms which is about 3 ms longer than that of the middle-ear muscle (MEM) reflex. This suggests that acoustic CTM reflex may have a longer neuronal chain than MEMs. The tuning curves of the 52 CTM fibres were of simple triangular shape and were very similar to one another. The best frequencies of these 52 fibres were between 28 and 43 kHz with an average value of 39±1.6 kHz. These tuning curves had sharper slopes both on the high and low frequency sides of the BF and thus had higher Q-10 dB values than that of the MEM fibres. The lowest minimum threshold of the CTMs is about 20 dB higher than the MEMs. When FM signals were delivered, the thresholds of the response were either higher or lower than the thresholds to pure tones depending upon the sweep range and sweep direction of the FM. On the average, a 10 kHz range of downward-sweep FM was 5 dB more effective than a pure tone, but a 20 kHz range of downward-sweep FM was only slightly better. A 10 or 20 kHz range of upward-sweep FM was usually not better than a pure tone. Furthermore, a 5 kHz or 30 kHz range FM signals sweeping either direction was always poorer than a pure tone. In Fig. 1, we present a representative tuning curve of a CTM fibre and its thresholds to FM signals at 10 and 20 kHz frequency sweep ranges. This fibre responded only in a small frequency band between 45 and 29 kHz. Its tuning curve shows a slope of 240 dB per octave and 140 dB per octave at its high and low frequency sides respectively. These slopes are much sharper than those obtained from the MEM fibres[7,10]. Note that the threshold for 10 kHz range downward-sweep FM is lower than pure tone and the equivalent upward-sweep FM. The threshold difference between the 10 kHz upward and downward sweep FM pulses was as large as 10 dB. The threshold for the 20 kHz range downward-sweep FM was almost the same as for the pure tone of 40 kHz, but the threshold for the equivalent 20 kHz upward-sweep FM was 9 dB less effective. The minimum threshold for this CTM fibre was 54 dB SPL.

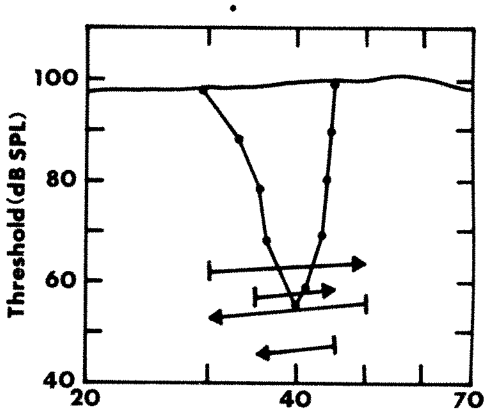

Fig. 1 The excitatory response area (solid line, filled circles) measured by 4-ms tone pulses with 0.5 ms rise and decay times and thresholds for FM tone pulses (arrows) of a representative CTM fibre. The ordinate and abscissa represent the stimulus amplitude in dB SPL (re 0.0002 dyne cm^{-2}) and frequency in kHz respectively. The uppermost solid line is a frequency response curve of the condenser loudspeaker used to deliver tone pulses. The arrows represent the directions of frequency sweeps of the 4-ms FM pulses. The different ranges of the FM sweep pulses are reprseented by the different lengths of the arrows and the thresholds of this CTM fibre for them are shown by the vertical positions of the arrows (see text for the properties of this fibre).

Fifty-one of the 52 CTM fibres studied had a threshold higher than 50 dB SPL and a narrow frequency response band between 45 and 25 kHz. Because of the frequency content of a bat's orientation sounds[1,2] and the highly directional sensitivity of its echolocation system[11] the acoustic CTM reflex of a bat will generally be evoked only by the sounds emitted by the bat itself or another bat which is flying toward this bat during the approaching or terminal phases. Returning echoes during the terminal phase may also evoke the reflex because their sound amplitudes may be higher than the threshold of this reflex. This speculation is supported by the present results that 10 or 20 kHz range of downward-sweep FM signals mimicking the natural orientation sounds during the final phase of flight were more effective stimuli than the corresponding upward-sweep FM signals or pure tones. An asymmetrical lateral inhibition at the low frequency side of the excitatory response area as that found in the collicular neurones and cortical neurones[12] may also exist in the CTM fibres which causes these fibres to be less sensitive to an upward FM stimulus than to a downward-sweep one.

This work was supported by a summer fellowship and a grant from the Research Council of the Graduate School, University of Missouri, Columbia, Missouri, and the Studienstiftung des deutschen Volkes from Federal Republic of Germany. We thank Professor N. Suga for his advice and providing the opportunity to conduct this work in his laboratory. We also thank Dr H. C. Gerhardt for reading this manuscript and giving valuable comments.

Suppression of noradrenaline synthesis in sympathetic nerves by carbidopa, an inhibitor of peripheral dopa decarboxylase

IT is generally believed that noradrenaline synthesis in postganglionic sympathetic nerves can be suppressed by drugs which inhibit the activities of tyrosine hydroxylase or dopamine β-oxidase[1,2], but not by inhibition of aromatic l-amino acid decarboxylase (AAAD; dopa decarboxylase). We present here evidence that the administration to rats of carbidopa (MK-486; α-methyl-L-dopa-hydrazine), a peripherally acting inhibitor of AAAD[3], not only blocks the decarboxylation of exogenous L-dopa (for example, in capillary endothelia within the central nervous system, liver, and kidney[4,5]), but also suppresses the decarboxylation of endogenous dopa formed from ^{3}H-tyrosine within cardiac sympathetic nerve terminals. As a consequence, the drug inhibits noradrenaline synthesis in this tissue.

Seven separate experiments, all yielding similar observations, were performed, using 122 normotensive male Sprague–Dawley rats (150–200 g) and 60 spontaneously hypertensive (SHR) male Wistar–Okamoto rats (Charles River Laboratories). In each experiment, groups of 4–10 rats received carbidopa (3.2–100 mg kg^{-1}, intraperitoneally, suspended in 0.05 N HCl or 0.9% saline) or its diluent, followed in 60 min by ^{3}H-tyrosine (80–100 μCi, in a total volume of 0.1–0.3 ml, intraperitoneally, specific activity 53.3 mCi μmol^{-1}, New England Nuclear). Animals were decapitated 60 min later and hearts were taken for assay of tyrosine[6], ^{3}H-tyrosine, ^{3}H-dopa and ^{3}H-catecholamines (including both ^{3}H-dopamine and ^{3}H-noradrenaline)[7,8]. (In preliminary studies we observed that the rates at which cardiac sympathetic terminals accumulate ^{3}H-dopa and ^{3}H-catecholamines are fairly linear during the 60-min interval used in these studies.)

Table 1 Effect of carbidopa on accumulation of ^{3}H-catechols in cardiac sympathetic nerves

	Control	Carbidopa
Tyrosine (μg g^{-1})	13.1 ± 0.42	28.9 ± 1.6*
^{3}H-tyrosine, specific activity ((d.p.m. μmol^{-1}) × 10^5)	7.2 ± 0.79	12.7 ± 1.1*
^{3}H-dopa (d.p.m. per g tissue)	173 ± 29	380 ± 29*
^{3}H-dopa/specific activity of ^{3}H-tyrosine ((μmol per g tissue) × 10^{-4})	8.3 ± 1.5	9.3 ± 6.1
^{3}H-catecholamines (d.p.m. per g tissue)	261 ± 26	155 ± 33†
^{3}H-catecholamines/spec. act. of ^{3}H-tyrosine ((μmol per g tissue) × 10^{-4})	11.5 ± 1.3	4.7 ± 1.0*

Groups of 20 male Sprague–Dawley rats received carbidopa (100 mg kg^{-1}, intraperitoneally) or its diluent, and, after 60 min, ^{3}H-tyrosine; the animals were killed 60 min later. Data are given as means ± s.e.m.

*$P < 0.001$ differs from control values.

†$P < 0.02$ differs from control values.

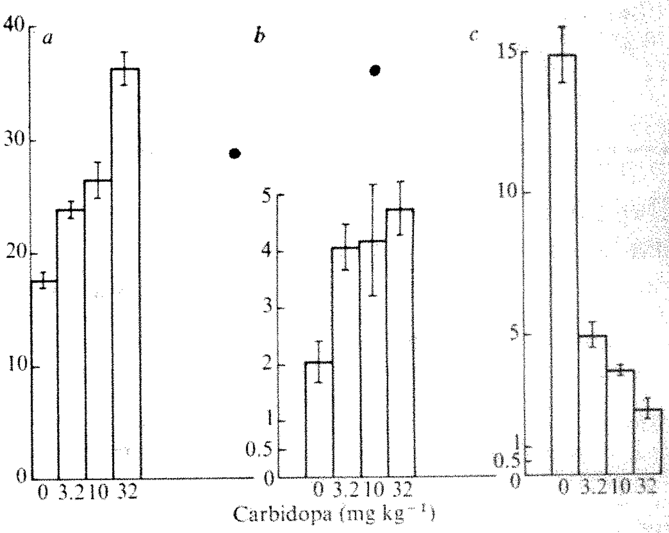

Fig. 1 Effect of carbidopa on the accumulation of ^{3}H-dopa and ^{3}H-catecholamines in hearts of SHR rats. Groups of eight rats were killed 120 min after receiving carbidopa or its diluent intraperitoneally, and 60 min after receiving ^{3}H-tyrosine (80 μCi; specific activity 53.3 mCi μmol^{-1}) intraperitoneally. Data are presented as ^{3}H-dopa (or ^{3}H-catecholamines) divided by the specific activity of cardiac ^{3}H-tyrosine. Vertical bars represent s.e.m. *a*, Tyrosine (μg g^{-1}); *b*, ^{3}H-dopa/specific activity of ^{3}H-tyrosine (μmol g^{-1} × 10^{-3}); *c*, ^{3}H-catecholamines/specific activity of ^{3}H-tyrosine (μmol g^{-1} × 10^{-4}).

In all our experiments, carbidopa at least doubled the concentration of tyrosine in cardiac homogenates (Table 1), and caused an even greater increase in cardiac ^{3}H-tyrosine. Thus it increased the specific activity of the ^{3}H-tyrosine present in the hearts (Table 1). For this reason, data on the amounts of ^{3}H-dopa and ^{3}H-catecholamines accumulating in the hearts were expressed both as d.p.m. per g of tissue and as μmol per g divided by the specific activity of the cardiac ^{3}H-tyrosine. Regardless of the method of data calculation used, the effects of the drug were the same, that is, it increased accumulation of ^{3}H-dopa and decreased that of ^{3}H-catecholamines. In experiments with normotensive rats (Table 1), concentrations of ^{3}H-dopa increased by 120% ($P<0.001$) and concentrations of ^{3}H-catecholamines decreased by 40% ($P<0.02$) when expressed as d.p.m. per g of tissue; these changes were +12% (not statistically significant) and −59% ($P<0.001$) when corrected for the specific activity of the ^{3}H-tyrosine.

SHR Wistar–Okamoto rats were found to be highly sensitive to the carbidopa inhibition of AAAD in cardiac sympathetic nerves: a concentration of the drug as low as 3.2 mg kg^{-1} almost doubled the accumulation of ^{3}H-dopa ($P<0.001$), and reduced ^{3}H-catecholamine accumulation by 60% ($P<0.001$) (Fig. 1). Larger doses of carbidopa were even more effective in these animals.

Administration of carbidopa reportedly has no effect on the AAAD in brain neurones of intact animals in the dose range used in our study[3,9,10]. In preliminary studies, we also failed to observe any suppression of brain ^{3}H-catecholamine synthesis (d.p.m. per g of tissue) in rats given ^{3}H-tyrosine and carbidopa. Thus, as far as we know, carbidopa may constitute the first clinically useful agent that suppresses noradrenaline synthesis in sympathetic neurones without significantly modifying brain catecholamine synthesis. Its effect on sympathetic nerves might underlie the ability of carbidopa to potentiate the antihypertensive actions of chemically diverse agents in spontaneously hypertensive rats[11]. Carbidopa might have value in the therapy of diseases involving peripheral catecholamines (or serotonin) in which the physician does not wish to modify brain function.

Dopamine is a monoamine oxidase B substrate in man

DURING the past decade, the central neurotransmitter, dopamine (DA), has been much studied for it is known to be involved in certain human disease states, Parkinsonism[1] preeminently, and rather more inferentially, schizophrenia[2]. DA is metabolised by monoamine oxidase (MAO)[3], which catalyses the oxidative deamination of a wide range of monoamines[4,5], including the neurotransmitters noradrenaline (NA) and 5-hydroxytryptamine (5-HT), and other amines such as tyramine, tryptamine and phenylethylamine (PEA). On the basis of animal studies with the inhibitors, clorgyline[6], and later deprenil[7], MAO has been classified into two types, A and B. By definition, type A is selectively inhibited by clorgyline and type B by deprenil. In general, type A acts on 5-HT[6] while type B prefers PEA[8]. In the rat, DA is preferentially deaminated by MAOA[9–11]. It thus seemed paradoxical that, in the treatment of Parkinsonism, addition of the MAOB inhibitor, deprenil, to a DA-generating drug combination should produce further therapeutic benefit[12]. In this report, we reconcile these apparently conflicting observations by demonstrating that, as far as DA oxidation is concerned, man may be different from rat: in two sites we have investigated, platelet and brain, DA is preferentially deaminated by an enzyme with the characteristics of MAOB.

Table 1 MAO activity of human platelets with PEA and DA as substrates

Subject	PEA	DA	DA:PEA
1	2.9	3.6	1.2
2	5.7	6.1	1.1
3	16.7	15.4	0.9
4	11.0	14.4	1.3
5	9.8	4.8	1.0
6	4.4	4.4	1.0
7	9.2	9.0	1.0
8	2.2	1.8	0.8
9	11.4	14.2	1.2
10	9.3	8.9	0.9
11	8.8	8.9	1.0
12	14.9	14.3	1.0
13	10.2	10.5	1.0

Activities are expressed as nmol of product formed per mg of protein per 30 min at 37 °C.

One way to trace the number and specificity of independent catalytic sites of MAO, which seem to vary both for tissue and species, is to do cross-inhibition experiments: White and Wu[13] used a wide range of substrates with human brain MAO and found extensive cross inhibition, apart from with PEA and 5-HT where there was none. Another approach, which we have used, is to see how activity varies when different substrates are used, whether with the same tissue from different individuals or with samples taken from different regions of the same individual. If only one catalytic centre deaminates a particular group of substrates, the ratio of activities should be constant.

We assayed MAO radiometrically by a cation exchange resin method for PEA[14], and an extraction procedure for DA and 5-HT[13]. The only modifications of existing methods were of scale: 100 μl of buffer was used with 20 μl of homogenate and 20 μl of substrate. The specific activities of the substrates were also increased fivefold and the final concentrations of DA or 5-HT in the incubation mixture was 150 μM, and of PEA, 50 μM. Incubations were carried out for 30 min at 37 °C and blanks with substrate but no enzyme and with boiled enzyme were incubated with each batch. The reaction was shown to proceed linearly for at least 30 min. Serial dilutions of clorgyline and deprenil in water were freshly prepared: 20 μl of each was added to 100 μl of buffer and 20 μl of enzyme suspension and left at room temperature for 30 min before starting the reaction with ^{14}C-DA. Platelets were collected from 10-ml venous blood samples collected into 10 ml of 2% EDTA in normal saline[15]. Normal human brains, obtained up to 48 h after death, were dissected, and separate regions were stored at −40 °C. Mitochondria and synaptosomes were prepared by differential centrifugation[16].

Human platelets have a type B enzyme which actively deaminates PEA[17]. This enzyme has low activity towards 5-HT and is inhibited by deprenil rather than clorgyline. Table 1 shows the activity of platelet MAO towards PEA and DA in samples chosen with widely different PEA-oxidising ability from different individuals. The PEA: DA ratio is constant whether absolute activities are high or low and the two activities are strongly correlated (r= 0.96). This indicates that the catalytic activities are controlled together and are probably located on the same molecule. The platelet enzyme is as active with DA as with PEA as substrate.

Table 2 shows the results of an experiment in which PEA, 5-HT and DA were used as substrates for MAO from several regions of a single human brain. Here the PEA: 5-HT ratio varied greatly from 16 in hypothalamic synaptosomes to 0.7 in substantia-nigral mitochondria, providing support for the existence of independent catalytic sites for 5-HT and PEA. There is clearly DA-oxidising activity in the regions of low 5-HT activity and in this brain it parallels that of PEA. In this brain there was a low 5HT: PEA ratio in the synaptosomal fraction.

We next examined the effects of clorgyline and deprenil

Table 2 MOA MAO activities in different regions of human brain with PEA, 5-HT and DA as substrates

Region	PEA	5-HT	DA	DA:PEA	PEA:5-HT	DA:5-HT
Synaptosomes						
Thalamus	25	9.1	31	1.2	2.7	3.4
Hypothalamus	72	4.5	60	0.8	16.0	13.0
Frontal cortex	13	4.4	11	0.8	3.0	2.5
Substantia nigra	49	29.0	55	1.1	1.7	1.9
Caudate	22	5.6	25	1.1	4.0	4.5
Mitochondria						
Thalamus	92	55	98	1.1	1.7	1.8
Hypothalamus	104	113	82	0.8	0.9	0.7
Frontal cortex	49	52	48	1.0	0.9	0.9
Substantia nigra	94	136	101	1.1	0.7	0.7
Caudate	71	44	73	1.0	1.6	1.6
Nucleus accumbens	75	35	67	0.9	2.1	1.9

Activities are expressed as nmol of product formed per mg protein per 30 min at 37 °C. Assays were carried out in duplicate.

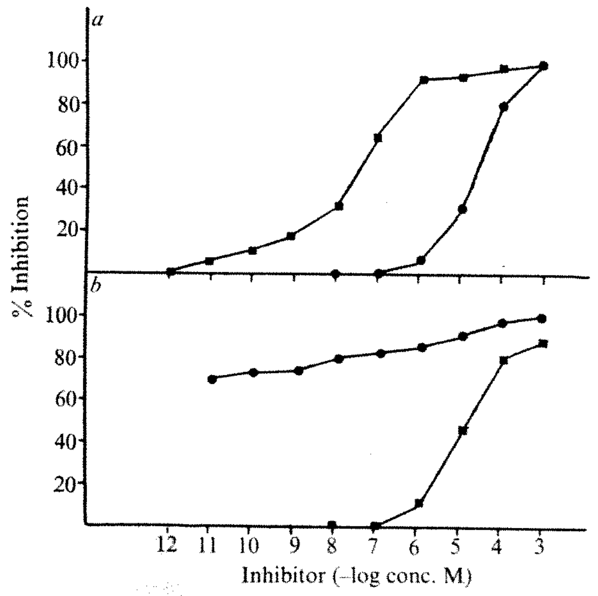

Fig. 1 Percentage inhibition of MAO activity plotted against concentration of deprenil (■) or clorgyline (●) in the incubation mixture, with DA as substrate. *a*, Human caudate mitochondria. Each point is the mean of values obtained using mitochondria from three brains. *b*, Rat brain. Each point is the mean of values obtained with homogenates from two brains.

on the DA-oxidising activity of human caudate mitochondria obtained from three brains. In each case it was selectively inhibited by deprenil (Fig. 1*a*). We also confirmed the finding[11] that the two inhibitors have the reverse effect on rat brain (Fig. 1*b*). Figure 2 shows the effect of deprenil on MAO from human putamen mitochondria, using 5-HT, PEA and DA as substrates. It demonstrates that the pattern of DA-oxidising activity resembles that of PEA rather than that of 5-HT. At low concentrations of deprenil, PEA and DA are selectively inhibited compared with 5-HT. The DA curve does not exactly follow that for PEA and both extend over several orders of magnitude. It may be that both substrates are oxidised by more than one form of MAO and that some of the DA-oxidising activity is also associated with that of 5-HT.

Although one cannot define the number of forms of MAO catalysing the oxidation of DA in the human striatum from these results, it is possible to draw the following conclusions. In man, DA oxidation can be independent of 5-HT-oxidising activity, a finding demonstrated most clearly in the platelet. In the human striatum, it is inhibited by smaller concentrations of deprenil than of clorgyline, resembling PEA-oxidising activity rather than that of 5-HT. This DA-oxidising mechanism seems to differ from that of rat brain although this tissue is inhomogeneous, an area with anomalous properties having been detected in the circumventricular region[18]. Other anomalous findings in rat[19] and beef[20] heart make the conclusion inescapable that MAO is more complex than the simple A/B classification suggests.

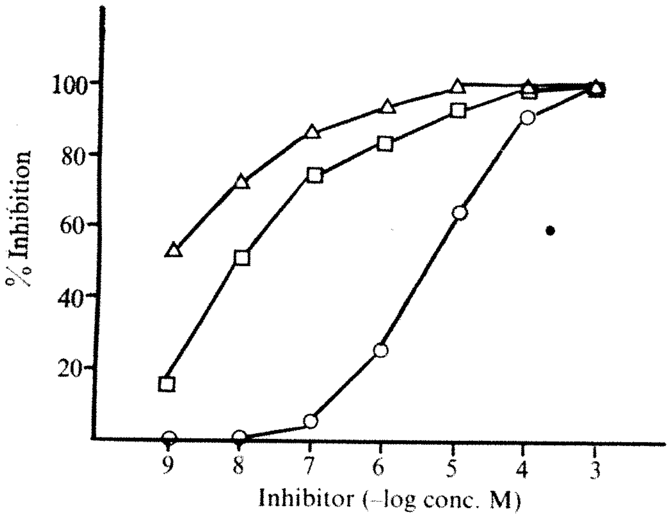

Fig. 2 Percentage inhibition of human putamen mitochondrial MAO activity plotted against concentration of deprenil in the incubation mixture with 5-HT (○), DA (□) and PEA (△) as substrates. Each point is the mean of values obtained by using mitochondria from two brains.

Whether the human enzyme shows similar variations from tissue to tissue awaits further investigation. As implied earlier, however, we have shown that the striatal enzyme has properties such that the addition of deprenil to a central dopamine-generating drug regimen[12] now seems to be a rational treatment of Parkinsonism.

We thank the Migraine Trust and the Rothschild Schizophrenia Research Fund for respectively defraying the salaries of V.G. and F.O. G.J.R. is a Sobotka Research Scholar. We thank Dr D. R. Maxwell for clorgyline and Professor J. Knoll for deprenil.

Concanavalin A as a carrier of daunomycin

ONE possible approach for increasing the effectiveness of anti-tumour drugs would be to find methods of altering their distribution in the body to increase their local concentration at the tumour cell sites. Ghose *et al.* have reported the suppression of Ehrlich ascites carcinoma in mice after administration of chlorambucil allegedly bound to anti-tumour antibodies[1]. This immunochemical approach to cancer has great potential, but the production of highly specific antibodies suitable for clinical use may prove to be a major practical problem.

Concanavalin A agglutinates and kills tumour cells *in vitro* under conditions where it has no such effect on normal cells. Administrated to mice it kills KHT fibrosarcoma tumour cells and, less markedly, AKR lymphoma cells at doses where it has no effect on numbers of normal hematopoietic colony forming cells[2]. The striking selectivity of con A prompted us to explore the possibility of using the drug as a carrier of daunomycin instead of specific anti-tumour antibody. We describe here the preparation of the conjugate and its striking anti-tumour activity.

Periodate oxidation of daunomycin was performed to cleave the bond between C-3 and C-4 of the sugar moiety, producing carbonyl groups capable of reacting with NH_2 groups on the con A and the resulting Schiff base linkages were reduced with $NaBH_4$ to form a peptide bond. Daunomycin 40 mg ml^{-1} in 1 ml of phosphate-buffered saline (PBS) was mixed with a slight molar excess of 0.1 mM $NaIO_4$ and incubated for 1 h at room temperature in the dark. Glycerol was then added to a final concentration of 0.05 M to consume excess periodate. The solution of oxidised drug was mixed with 1 ml of con A 15 mg ml^{-1} in 0.15 M potassium phosphate buffer (*p*H 9.5) and incubated for 1 h at room temperature. $NaBH_4$ was then added to a final concentration of 0.3 mg ml^{-1}, and the reaction was allowed to proceed for 1 h at 37 °C[3]. Free and bound drugs were separated by gel filtration chromatography, using Sephadex G-100. The degree of substitution was estimated by the drug absorbance at 495 nm and protein concentration was assessed by optical density at 280 nm. The extent of substitution was 2 to 3 mol daunomycin per mol con A. Concanavalin A–daunomycin conjugate was dialysed against PBS for several hours and *in vivo* studies were performed within 24 h. Agglutination assays for sheep erythrocytes were performed in a final volume of 250 μl of PBS at a cell concentration of 1×10^8 cells per ml. Con A and con A–daunomycin conjugate equally agglutinated the erythrocytes at the minimum concentration of 2 μg ml^{-1}. SDS polyacrylamide disc gel electrophoresis of the conjugate revealed one protein band with molecular weight about 26,000.

Table 1 Survival of BDF_1 mice bearing L_{1210} cells

Daily treatment (i.p.) (days 1–5)	Mean survival time (d)
Control	7.0
Daunomycin (0.4 mg kg^{-1})	7.4
Con A (8 mg kg^{-1})	7.2
Con A (8 mg kg^{-1}) + Daunomycin (0.4 mg kg^{-1})	7.2
Con A–daunomycin (8 mg kg^{-1})	11.4
Con A–daunomycin (8 mg kg^{-1}) + Hydrocortisone (2 mg kg^{-1})	11.2

To show the effectiveness of the conjugate as an antitumour agent *in vivo*, several groups of five BDF_1 mice were inoculated with 1×10^5 live L_{1210} cells intraperitoneally and BALB/c mice were inoculated with 2.5×10^6 live Ehrlich ascites carcinoma cells intraperitoneally. After 24 h the mice received the first of five daily injections of the conjugate and control preparations. Table 1 and 2 show the results of such experiments. The greatest increase in survival was obtained when the conjugate was given and Ehrlich ascites carcinoma cells were more sensitive to the conjugate than L_{1210} cells.

Table 2 Survival of BALB/c mice bearing EAC cells

Daily treatment (i.p.) (days 1–5)	Mean survival time (d)
Control	23.6
Daunomycin (0.1 mg kg^{-1})	25.6
Con A (2 mg kg^{-1})	27.2
Con A (2 mg kg^{-1}) + Daunomycin (0.1 mg kg^{-1})	27.8
Con A–daunomycin (2 mg kg^{-1})	all alive
Con A–daunomycin (2 mg kg^{-1}) + Hydrocortisone (1 mg kg^{-1})	all alive

One volume of tumour cell suspensions (1×10^7 cells per ml of PBS) were mixed with 1 volume of concanavalin A solution (375 μg per ml of PBS). After manual shaking, the mixtures were incubated at room temperature for 1 h and the cell aggregates consisting of more than three cells were counted. The aggregated cells of Ehrlich ascites carcinoma and L_{1210} were 36 and 10 per 200 cells respectively. There may exist some relationship between cell agglutinability by con A *in vitro* and sensitivity to the conjugate *in vivo* although the precise mechanism is not known.

Con A is a potent mitogen for mouse lymphocytes *in vitro*, therefore the conjugate may be toxic for mouse lymphocytes. Steroid hormone inhibits T cell response to mitogen. Intracutaneous injection of con A induces the haemorrhagic Arthus-like lesions[4] which can be inhibited with steroid hormone. Hydrocortisone was given simultaneously with the conjugate to inhibit lymphocyte damage and Arthus-like lesions and did not inhibit the antitumour activity of the conjugate (Tables 1 and 2).

The con A–daunomycin conjugate may be sufficiently toxic and selective in its effect to be potentially useful in *in vivo* therapeutic studies.

Recognition sequence of specific endonuclease *Bam*HI from Bacillus amyloliquefaciens H

MANY specific endonucleases (restriction endonucleases) have been isolated and recognition sequences have been determined for a number of them[1]. The isolation of a new specific endonuclease, *Bam*HI, from *Bacillus amyloliquefaciens* H has recently been described[2]. We have determined the recognition sequence of *Bam*HI and find that it cleaves the two-fold rotationally symmetric sequence

↓
5′-G-G-A-T-C-C-3′
3′-C-C-T-A-G-G-5′
↑

at the positions indicated by the arrows generating fragments with cohesive termini.

The *Bam*HI used for these experiments was purified and used as described previously[2]. This endonuclease gives relatively few fragments from most viral DNAs and, to ensure a statistically significant sampling, parallel experiments were carried out on bacteriophage λ DNA (five sites)[2], adenovirus-(Ad-2) DNA (three sites)[2] and Φ 80suIII+ DNA (eight sites). The experiments described in detail used Ad-2 DNA, which

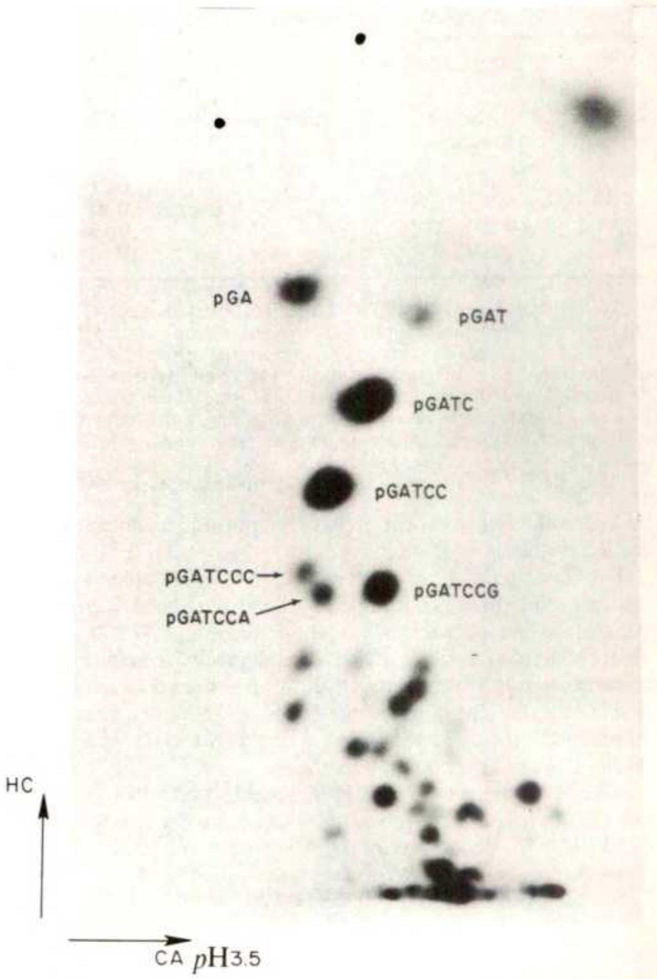

Fig. 1 Pancreatic DNase digestion products of 5′-terminally labelled *Bam*HI fragments. Ad-2 DNA (10 μg) was incubated in a reaction mix (100 μl) containing 6 mM Tris-HCl pH 7.9, 6 mM $MgCl_2$, 6 mM 2-mercaptoethanol and 10 units *Bam*HI for 1 h at 37 °C. Alkaline phosphatase (5 μg) was added, the volume increased to 150 μl by adjusting to 50 mM Tris-HCl, pH 8.9, 10 mM $MgCl_2$ and incubation continued for a further 1 h at 37 °C. Following extraction with phenol (4 × 150 μl), the DNA fragments were precipitated with EtOH and recovered by centrifugation (20 min, 100,000g). The DNA was phosphorylated in a reaction mix (100 μl) containing 50 mM Tris-HCl pH 9.5, 10 mM $MgCl_2$, 5 mM dithiothreitol, 5% glycerol, 10 μM γ-^{32}P-ATP (specific activity 1,000 $\mathrm{C_i mmol^{-1}}$) and 10 units polynucleotide kinase (Biolabs) and incubated for 1 h at 37 °C. Unreacted γ-^{32}P-ATP was removed by passage over a Sephadex G-50 column run in 0.1 M NaCl, 0.01 M Tris-HCl, pH 7.9, 0.001 M EDTA. Labelled *Bam*HI fragments were recovered from the void volume by precipitation with EtOH (2 volume) and centrifugation (20 min, 100,000g). The DNA was then incubated in a reaction mix (20 μl) containing 0.1 M NaOAc pH 5.0 and pancreatic DNAse (5 μg) for 30 min at 37 °C, and lyophilised. This reaction mixture was redissolved in H_2O (3 μl) and fingerprinted using electrophoresis on cellulose acetate at pH 3.5 in the presence of 7 M urea for the first dimension followed by homochromatography[5] on a thin layer of DEAE-cellulose (1:10) eluting with homomix VI[6] for the second dimension. The 5′-terminal oligonucleotides were detected by autoradiography, and their sequences deduced from mobility shifts and also as indicated in the text. Oligonucleotides, used for further digestion, were eluted from the thin layer plate in the conventional way[5].

cannot be labelled with polynucleotide kinase prior to restriction endonuclease cleavage (R. J. R., unpublished results), thus avoiding problems of interpretation due to labelling at the ends of the viral genome. The sequences present at the 5′ termini of the *Bam*HI fragments were analysed as follows: Ad-2 DNA was digested with *Bam*HI, the 5′-terminal phosphate was removed by treatment with alkaline phosphatase (an obligatory step) and replaced by a ^{32}P-phosphate using polynucleotide kinase[3] and γ-^{32}P-ATP[4]. The labelled *Bam*HI fragments were digested with pancreatic DNAse and the resulting oligonucleotides fractionated by electrophoresis on cellulose acetate at pH 3.5 in the presence of 7 M urea, followed by homochromatography[5] using homomix VI[6]. An autoradiograph of the resulting fingerprint is shown in Fig. 1.

Table 1 Identification of the 5′-dinucleotide present after cleavage with *Bam*HI

Dinucleotide	R_B (System 1)	R_Y (System 2)
pGA	1.62	0.59
pGC	1.76	0.47
pGG	1.10	0.69
pGT	1.03	0.82
*Bam*HI product	1.63	0.59

The four standard dinucleotides were prepared by phosphorylating the corresponding dinucleoside monophosphates (Collaborative Research) with polynucleotide kinase (Biolabs) and γ-^{32}P-ATP as described in the legend to Fig. 1 and purifying the products by electrophoresis on DEAE-cellulose paper in 7% formic acid (System 1). Oligonucleotides from the fingerprint shown in Fig. 1 were incubated in a reaction mix (20 μl) containing 66 mM glycine-NaOH pH 9.6, 6.6 mM $MgCl_2$, 3.3 mM dithiothireitol and 10 units exonuclease I for 30 min at 37 °C, and spotted on the appropriate paper for fractionation. The oligonucleotide labelled pGA in Fig. 1 was unaffected by this treatment and was identical with the products of digestion of all longer oligonucleotides. System 2 consisted of electrophoresis on Whatman 540 paper at pH 3.5 (ref. 8). R_B refers to the electrophoretic mobility with respect to that of the blue dye xylene cyanol FF[8] and R_Y to the yellow dye orange G[8].

The dinucleotide pGA was identified by (1) digestion with venom phosphodiesterase which liberated only pG; (2) its resistance to the action of exonuclease I[7]; and (3) direct comparison with the four standard dinucleotides pGN (Table 1). The sequences of longer oligonucleotides were inferred from their mobility shifts[9] and suggest a unique pentanucleotide pGATCC present at the 5′ end of each *Bam*HI digestion product. The presence of three of the four possible hexanucleotides pGATCCN indicates that specificity is lost at the sixth position—the absence of the fourth possible sequence being caused by the small number (six) of termini present in the digest used for this experiment. When λ DNA and $\Phi80suIII^+$ DNA were used in parallel experiments, all four possible hexanucleotides were observed (data not shown).

The simplest interpretation of these results is that *Bam*HI is recognising the hexanucleotide

$$\begin{array}{c} \phantom{5'\text{-}}\downarrow\phantom{\text{-A-T-C-C-3'}} \\ 5'\text{-G-G-A-T-C-C-3'} \\ 3'\text{-C-C-T-A-G-G-5'} \\ \phantom{3'\text{-C-C-T-A-}}\uparrow\phantom{\text{-G-5'}} \end{array}$$

with the sites of cleavage as indicated by the arrows. This would mean that *Bam*HI fragments possess a 5′-tetranucleotide extension and hence should be a substrate for a DNA polymerase. This prediction was tested by preparing *Bam*HI fragments of Ad-2 DNA and incubating them with avian myeloblastosis virus (AMV) reverse transcriptase in the presence of one α-^{32}P-deoxynucleoside triphosphate and three unlabelled deoxynucleoside triphosphates. All four possible combinations were used and the products were analysed by nearest-neighbour analysis. The results of these experiments are shown in Table 2

Table 2 Nearest neighbour analysis of nucleotides incorporated into *Bam*HI treated Ad-2 DNA by AMV reverse transcriptase

Labelled substrate	pmol ^{32}P-dNTP incorporated		Products of micrococcal nuclease and spleen phosphodiesterase digestion†				Sequence deduced (5′→3′)
	*Bam*HI treated Ad-2 DNA*	Ad-2 DNA*	Cp	Ap	Gp	Tp	
α-^{32}P-dATP	7.2 (6)	0.21 (0)	18	16	62	4	GpA
α-^{32}P-dCTP	6.8 (6)	0.10 (0)	13	12	10	65	TpC
α-^{32}P-dGTP	7.8 (6)	0.16 (0)	18	17	52	13	GpG
α-^{32}P-TTP	7.1 (6)	0.13 (0)	15	54	18	13	ApT

*Bam*HI fragments of Ad-2 DNA and untreated Ad-2 DNA were used as templates for the incorporation of one α-^{32}P-deoxynucleoside triphosphate and three unlabelled deoxynucleoside triphosphates with AMV reverse transcriptase. 23 μg (1 pmol Ad-2 DNA) of fragments were used in each experiment using conditions previously described[10]. An aliquot of the reaction mixture was precipitated with perchloric acid to determine the total incorporation. The resulting labelled DNA was completely digested with micrococcal nuclease and spleen phosphodiesterase[11] and the resulting mono-nucleoside 3′-phosphates analysed by electrophoresis on Whatman 540 paper at *p*H 3.5. The separated mononucleotides were visualised by radioautography, cut from the paper and quantitated by liquid scintillation counting.

*The number in parenthesis is the theoretical incorporation calculated from the deduced sequence and for the three *Bam*HI sites present in Ad-2 DNA.

†Quantities of 3′-mononucleotides expressed as a percentage of the total mononucleotides detected.

and provide confirmation of the recognition sequence assigned earlier on the basis of mobility shifts.

The data from these experiments involving repair synthesis indicate that there is some heterogeneity at the 3′ terminus in contrast to the homogeneity at the 5′ terminus. The amount of heterogeneity observed varied considerably from one experiment to another and is most easily interpreted as due to the presence of a contaminating 3′→5′ exonuclease (similar to exonuclease III of *Escherichia coli*)[12] present in the preparation of *Bam*HI used for these experiments.

Like *Eco*RI[13] and *Hind*III[14], *Bam*HI generates fragments bearing cohesive termini. This should prove useful for the production of recombinant DNAs and a vector suitable for *Bam*HI fragments has already been described[15].

Exonuclease I was a gift from R. Wu.

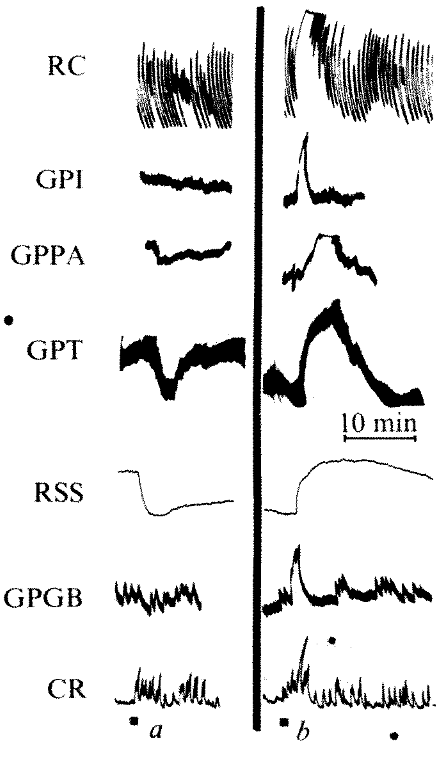
Relationship of spasmogenic and smooth muscle relaxant peptides from normal lung to other vasoactive compounds

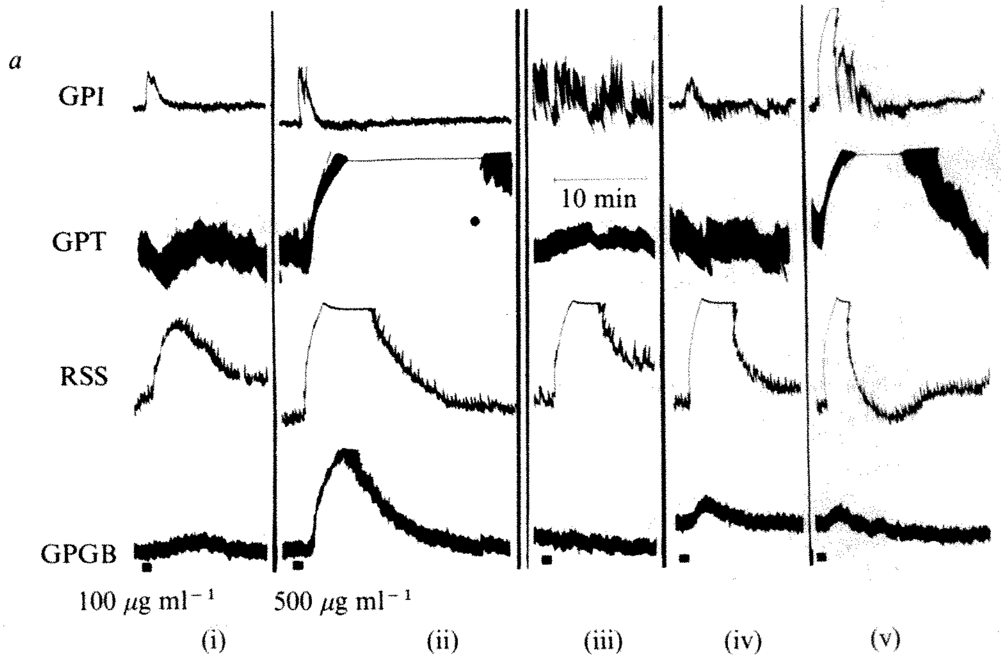
ALTHOUGH abnormal lung tissue, especially certain bronchogenic tumours, may secrete a variety of peptide hormones[1], none has been isolated from normal lung. We have now extracted from normal hog lungs peptide fractions containing at least two active principles, one of which relaxes and the other contracts non-vascular smooth-muscle organs. Like the recently isolated vasoactive intestinal peptide (VIP)[2], both pulmonary peptide fractions are systemic vasodilators. The relaxant peptide fraction further resembles VIP in its smooth-muscle effects, and binds with antibodies against this peptide. The spasmogenic peptide fraction contracts a variety of smooth-muscle organs that are also contracted by prostaglandins, bradykinin, angiotensin II, substance P, and the "slow-reacting substance of anaphylaxis". Immunoreactivity attributable to the relaxant, VIP-like peptide, was found in normal lungs of several mammals, including man, and in pulmonary oedema foam.

Fig. 1 Responses of isolated, superfused smooth-muscle organs to 125 μg ml^{-1} of *a*, relaxant and *b*, spasmogenic lung peptide fractions, infused at 1 ml min^{-1} (data from two experiments). RC, rat colon; GPI, guinea pig ileum; GPPA, guinea pig pulmonary artery; GPT, guinea pig trachea; RSS, rat stomach strip; GPGB, guinea pig gall bladder; CR, chick rectum. Assay organs had been pretreated with a mixture of pharmacological blockers containing: 10^{-7} g ml^{-1} mepyramine maleate, 2×10^{-7} g ml^{-1} methysergide bimaleate, 2×10^{-6} g ml^{-1} propranolol HCl, 10^{-7} g ml^{-1} phenoxybenzamine HCl, and 10^{-7} g ml^{-1} of hyoscine HBr. Peptide solutions were infused at mark below. Upward movement is contraction, and downward movement relaxation.



The extraction procedures were similar to those used in the isolation of VIP[3]. Fresh hog lungs were boiled for 10 min, minced and extracted in dilute acetic acid. The filtered extract was treated with alginic acid to adsorb peptides, which were later eluted with HCl, salted out with NaCl and extracted with methanol. During these procedures, repeated washing with lipid solvents ensured the removal of prostaglandins and other lipids. From the methanol extract, peptides were recovered in aqueous solution and then desalted and fractionated on a column of Sephadex G-25, with dilute acetic acid as eluant. The active fractions were chromatographed on a column of carboxymethyl cellulose (CMC), using phosphate buffer (*p*H 6.4) and a gradient of NaCl. Further purification of the smooth-muscle relaxant peptide fraction was obtained by a second chromatography on CMC, at *p*H 8, followed by counter-current distribution in a 1:1 mixture of 0.1 M ammonium bicarbonate and *n*-butanol.

During the extraction and purification, test solutions were assayed by their vasodilator action on the systemic circulation of anesthetised dogs[4], and by their effects on isolated, superfused smooth-muscle organs[5]. The active peptide fractions induced peripheral vasodilation, evidenced by an increase in femoral blood flow and a fall in aortic blood pressure on infusion into the femoral artery. When tested on smooth-muscle organs, these fractions were found to contain two active principles, having opposite actions. Thus, one fraction contracted, and the other relaxed: stomach strip and colon of rat; trachea, pulmonary artery, ileum and gall bladder of guinea pig; and chick rectum (Fig. 1). These effects were dose-related (Figs 2 and 3), were unaltered by pharmacological blockade of histamine, 5-hydroxytryptamine, adrenergic or cholinergic receptors, but were almost totally abolished by incubation with the proteolytic enzyme pronase (Calbiochem, 20 μg per mg peptide fraction).



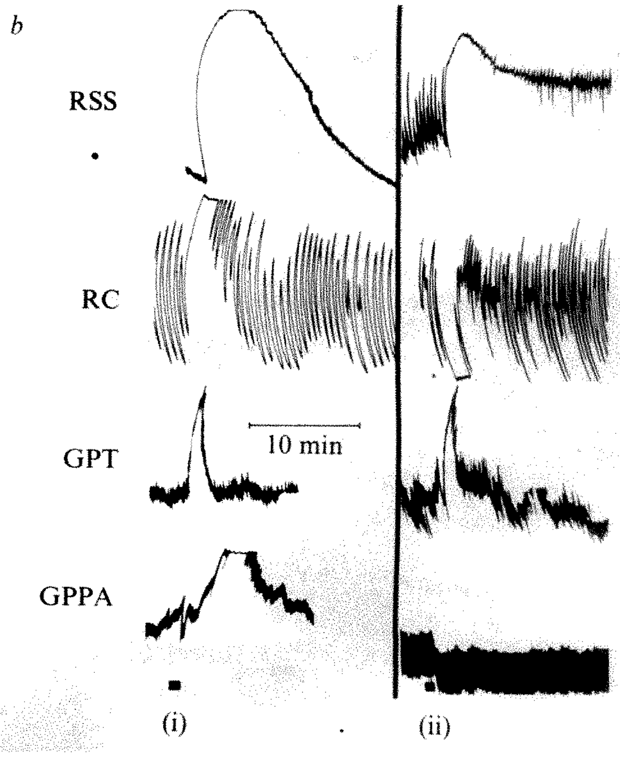


Fig. 2 *a*, Responses of guinea pig ileum (GPI), guinea pig tracea (GPT), rat stomach strip (RSS), and guinea pig gall bladder (GPGB) to two doses (100 and 500 μg ml^{-1}) of spasmogenic lung peptide fraction (i and ii) and to prostaglandin $F_{2\alpha}$ (50 ng ml^{-1}) (iii), prostaglandin E_2 (5 ng ml^{-1}) (iv) and substance P (1 μg ml^{-1}) (v). All agents were dissolved in Krebs solution and infused at 1 ml min^{-1}. *b*, Responses of RSS, rat colon (RC), GPT and guinea pig pulmonary artery (GPPA) to same spasmogenic peptide fraction (125 μg ml^{-1}) (i) and to bradykinin (50 ng ml^{-1}) (ii).

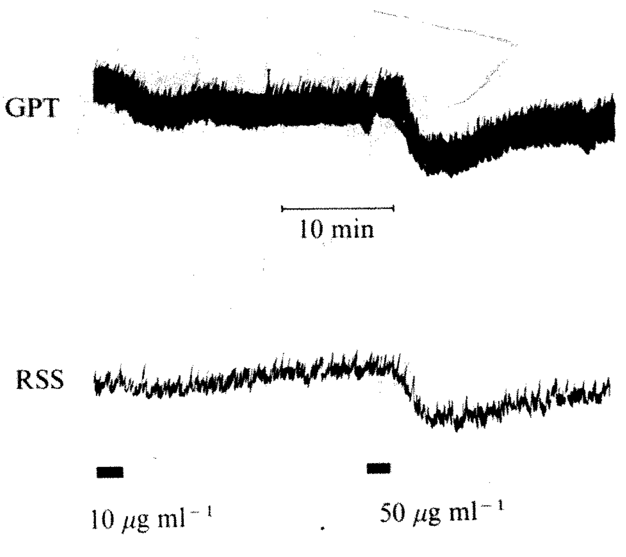
The smooth-muscle actions of the relaxant lung peptide fraction are similar to those of VIP, which relaxes the above-listed smooth muscle tissues[6,7]. This lung peptide fraction also competed with labelled VIP in binding to anti-VIP antibodies in a radioimmunoassy that detects 20 pg of the porcine peptide per ml[8,9]. With progressive purification, culminating in countercurrent distribution, this binding capacity increased along with the increase in biological activity and was at least 15% that of pure porcine VIP. The displacement of bound VIP with different dilutions of this peptide paralleled the standard curve for pure VIP. In the same assay, antibodies to VIP showed less than 1:1,000 cross reaction with secretin (GIH Laboratory, Karolinska Institute), glucagon (Eli Lilly), cholecystokinin–pancreozymin (GIH Laboratory), bradykinin (Sandoz), substance P (Beckman), or somatostatin (ovine, Beckman).

The spasmogenic peptide fraction, on the other hand, exhibited negligible ($<0.1\%$) binding capacity to VIP antibodies. The smooth-muscle actions of this peptide fraction resembled those of other vasoactive substances (Fig. 2), but could be distinguished from these by examination of the full spectrum of biological activity. Thus, prostaglandin E_2 in a dose (5 ng ml^{-1}) giving nearly equal contraction of guinea pig ileum, relaxed guinea pig trachea and gave a stronger contraction of rat stomach strip. Prostaglandin $F_{2\alpha}$ (50 ng ml^{-1}) contracted guinea pig trachea but was without effect on ileum and gall bladder. Substance P, in a dose (1 μg ml^{-1}) causing a stronger contraction of ileum, was less active on gall bladder and trachea. The spasmogenic lung peptide could also be distinguished from bradykinin, which relaxed rat colon and a strip of guinea pig pulmonary artery, and from angiotensin II, which is a vasoconstrictor. The incompletely identified "slow-reacting substance of anaphylaxis", was not available to us for comparison. This substance has been detected and assayed in biological solutions and tissue extracts on the basis of contraction of guinea pig ileum or trachea, in the presence of atropine and an antihistaminic[10]. These actions alone do not, however, permit a differentiation between the slow-reacting substance and the spasmogenic lung peptide.

Because of the above findings in purified peptide fractions from lung, crude extracts of normal lung from several species (dogs, cats, rabbits, and human subjects undergoing thoracic surgery) were examined for VIP-like immunoreactivity. The extracts, prepared by boiling for 10 min and extracted in acid alcohol, contained the equivalent of up to 2.8 ng immunoreactive VIP per g wet weight. On induction of pulmonary edema in anesthetised cats (by rapid intravenous infusion of dextran–saline solution) or in isolated, perfused cat lungs (by raising outflow pressure), oedema fluid and foam contained approximately 300 pg ml^{-1} of VIP immunoreactivity.

Fig. 3 Dose-related relaxation of guinea pig tracea (GPT) and rat stomach strip (RSS) in response to infusion of 10 and 50 μg ml^{-1} of relaxant peptide fraction.



The apparent presence in the lung of a VIP-like peptide may be explained by the embryological derivation of the lung from foregut, or by the presence of neuro-endocrine (APUD) cells, of neural crest origin, in the lung as well as the gastrointestinal tract[11]. This observation is another example of the occurrence of VIP-like bioactivity and immunoreactivity outside the gastrointestinal tract; related activity has recently been found in high concentrations in the brain and other nervous tissue[9]. The presence of two peptides with opposing actions on tracheobronchial and vascular smooth muscle (and other contractile elements in lung[12]) provides a potential mechanism for regulating the distribution of alveolar ventilation and perfusion. The demonstration of one of the vasoactive lung peptides in pulmonary oedema foam suggests that this, and possibly also the other peptide, may be released in clinical settings associated with pulmonary oedema, for example heart failure, "respiratory distress syndromes", oxygen poisoning, and anaphylaxis. The recent finding of increased plasma VIP immunoreactivity in some patients with lung tumours[8] could have been due to secretion of the VIP-like pulmonary peptide.

Because of the similarities in biological actions between the spasmogenic lung peptide, other vasoactive peptides (bradykinin, angiotensin II and substance P), the prostaglandins, and the "slow-reacting substance of anaphylaxis", the possibility of release of this peptide should be considered whenever spasmogens are released from the lung. The use of multiple bioassay organs should help to distinguish between the different compounds, especially if they are present singly.

This work was supported in part by a Lung Center Award from the National Heart and Lung Institute of the US Public Health Service, and by a grant from the Swedish Medical Research Council. We thank M. Rifaat, L. Melin, K. Thermaenius and T. V. Nguyen for assistance.

Historical essays on mycology

C. T. Ingold

Introduction to the History of Mycology. By G. C. Ainsworth. Pp. xi+359. (Cambridge University: Cambridge, London and New York, 1976.) £11.

MYCOLOGISTS have always lacked a comprehensive history of their subject. Many of the older mycologists have read with profit Whetzel's *An Outline of the History of Phytopathology* (1918) and have relished Ramsbottom's *The Expanding Knowledge of Mycology Since Linnaeus* (1941). And a much wider circle has also rejoiced in Large's *The Advance of the Fungi.* But now at last here is a full-scale history of mycology, although, with characteristic modesty, the author presents it as an *Introduction.*

Only one with an encyclopaedic knowledge of the literature on fungi could have produced this work which fittingly comes from the pen of one who can be described as the Dr Johnson of mycology. No other worker in this field can exist without almost daily reference to his *Dictionary of Fungi.*

Dr Ainsworth has sensibly not attempted to keep all sections of the subject in play while proceeding steadily from the earliest times to the present day, but has rather produced a series of historical essays on various aspects of mycology. These form his chapter headings: origin and status of fungi; form and structure; culture and nutrition; sexuality, cytology and genetics; pathogenicity; poisonous, hallucinogenic and allergenic fungi; classification; and finally the organisation of mycology.

Mayan mushroom stone (British Museum, London), probably from Guatemala and believed to date from the middle of the first millenium AD—early evidence for a mushroom cult in Central America.

P. A. Micheli, born in 1679 and the author of *Nova Plantarum Genera* (1729), is rightly regarded as starting the scientific study of the fungi; as the father of mycology. We learn from the English translation of his epitaph in Florence that he "was much beloved by all the worthy men of his age on account of his wisdom, sweetness of disposition and modesty". A number of figures from his magnum opus are reproduced: the full title-page; his lovely plate of *Clathrus;* his representation of agaric structure and development: his drawings of almost pure cultures of moulds on melon slices; his illustrations of *Aspergillus* and *Botrytis;* and his dynamic figure of a cup-fungus puffing. Also reproduced are Micheli's original drawings of asci, the first ever made, showing clearly that the blockmaker did a rather poor job at times in preparing the plates for the printed book.

There is a basic difficulty about a history that extends from the misty past to the present. In the earlier part much must be made from very little: and in the more recent part there is such a wealth of material that the historian is faced with an almost impossible task of selective condensation. It is, of course, easy to criticise this selection from recent history. For example, in connection with mycorrhiza no mention is made of Melin's work and the reader is referred for a recent view on ericaceous mycorrhiza to a 1927 review by Rayner! Again, in the genetics section the early work of Hansen and Smith in 1932 on heterokaryosis does not figure; indeed, the word does not occur in the index. But any criticisms of this nature are of marginal significance.

The chapter on pathogenicity is particularly rewarding because the author, with his profound knowledge of medical and veterinary mycology, presents a balanced picture in which diseases of plants and of animals (including man) are nicely balanced. Occasionally, perhaps inevitably, a chapter becomes something of a catalogue and this is most noticeable in the chapters on the distribution of fungi and on classification.

Illustrations are a special feature of the book. In all, 106 carefully selected figures—including reproductions of historic drawings; portraits and photographs of eminent mycologists; and facsimile reproductions of pages from books and manuscripts—provide a distinguished atmosphere for the book.

A brief section which many will enjoy deals with hallucinogenic fungi. The Wassons together with Roger Heim are regarded as the founders of ethnomycology.

The final chapter on the history of the organisation of the subject is stimulating. It is concerned with mycological societies, journals and books. Due credit is given to de Bary's textbook. Although over a hundred years old, this great work is still a model that has never been surpassed and is still an inspiration to working mycologists. The same chapter is enlivened by one of Worthington Smith's delightful cartoons of fungal forays a century ago.

Another mycologist writing a history (but it is difficult to think of anyone else who could do it) would certainly achieve a different balance. To some extent the balance reflects Dr Ainsworth's own interests but happily these are exceptionally wide. It is perhaps not a book for the undergraduate student, but it will be read with enormous pleasure by all mycologists with a broad interest in their subject. Every library in an institution where fungi are studied will have to possess a copy and many individual workers will want one of their own. ☐

C. T. Ingold was Professor of Botany at Birkbeck College, University of London, UK, from 1944 to 1972.

Insect integuments

The Insect Integument. Edited by H. R. Hepburn. Pp. xix+571. (Elsevier Scientific: Amsterdam, Oxford and New York, 1976.) Dfl.165.00. $63.50.

THIS *Festschrift* is dedicated to A. Glenn Richards, author of the classic *Integument of Arthropods* (1951) and constructor of the first electron microscope ultramicrotome (1942). In a biographical first chapter, M. Rockstein describes the life and work of 'Glenn', including a bibliography. The miscellany of 26 papers naturally contains much that is already well-known. In the space here available I have therefore selected those items whose originality impressed me.

K. M. Rudall presents excellent X-ray diffraction diagrams from cuticles and from *Sagitta* (Chaetognatha) spines. Had one been more fully Miller-indexed, however, it would make the text easier to follow. V. Strout, H. Lipke and T. Geoghegan show by formic acid extraction a narrowing of the range of molecular weights of chitin as the last larval cuticle becomes that of the puparium in flies. This facilitates chitin reorientation at this stage.

In an invigorating chapter, R. A. A. Muzzarelli provides a useful collateral of chemical knowledge from fungal and bacterial research. This includes native chitosan, and the enzymes responsible for its formation from chitin and subsequent degradation. He also reviews chitin—carotenoid linkage in cuticles, and new insecticides acting as inhibitors of chitin synthesis, rightly warning of the danger of their indiscriminate use.

V. B. Wigglesworth emphasises the possible significance of lipids as structural polymers in cuticle. There follows a pioneer attempt (R. H. Hackman) to explain the large number of protein species in cuticles as polymorphism, due to substitution mutations in the second base of genetic code triplets. But the supporting evidence seems to require statistical analysis. S. O. Andersen provides a comprehensive review of cross-linking enzymes both in haemolymph and the cuticle itself. P. Karlson and C. E. Sekeris review the morphogenetic action of ecdysone, augmenting their classical results with recent evidence. P. J. S. Furneaux and A. L. Mackay describe a 90° cross-ply fibril array in a beetle eggshell, the first in insects, as far as I am aware. R. Dennell revives a mechanistic theory for contol of chitin orientation, but does not mention existing published evidence against it. H. R. Hepburn and I. Joffe have compiled useful and detailed tables of mechanical properties for chitin and whole cuticle. On the basis of stress–strain curves and fractography they distinguish cuticles which show plastic fracture, brittle fracture, or a combination of both. M. Locke relates cuticle formation to alternate secretion by plasma membrane plaques and Golgi vesicles.

S. Caveney presents results which may shed light on the unsolved problem of cell morphogenetic gradients. He shows that insect epidermis functions as a syncytium by cell/cell communication via gap junctions. The late J. M. Whitten records the regular orientation of centriole-like structures in the cells of fly feet, and suggests that they may be related to formation of regular hair patterns. E. P. Marks and B. A. Sowa are successfully exploiting *in vitro* cuticle growth methods for investigating blocks to chitin synthesis and effects of insecticides on cuticle formation under carefully controlled conditions. Chapters by H. Nemenz and W. Ebeling both stress the importance of epidermis rather than epicuticle as a water-controlling mechanism in relation to osmoregulation and insecticides respectively.

J. F. V. Vincent compares stress-softening in locust intersegmental membrane and filled rubber composites, while H. C. Bennet-Clark provides a lucid account of jumping principles and cuticular energy storage mechanisms. F. G. Barth summarises results of photoelastic analysis of strains applied to perspex models of the cuticular parts of arachnid mechanoreceptors. Ablation experiments have pinpointed the specific sense organs predicted to be responsible for the idiothetic sense of spiders. This is the sense of orientation using the experience of previous movement sequences, without using landmarks. H. E. Hinton reviews a wide range of recent work on insect physical colour systems. He records anti-reflection nipples (previously thought to be restricted to corneal surfaces) on the wing scales of the green hairstreak butterfly. W. Kenchington presents an intriguing range of modes of formation of peritrophic membranes. W. Peters summarises recent results on *in vitro* growth of peritrophic membrane, and factors which affect it.

The volume is well produced and will clearly be necessary reading for relevant workers—if their institutions can afford it. **A. C. Neville**

Dr Neville is a Reader in Zoology at the University of Bristol, UK.

Atmospheric radiative transfer

Radiative Processes in Meteorology and Climatology. (Developments in Atmospheric Science, Vol. 5.) By G. W. Paltridge. Pp. xvii+318. (Elsevier Scientific: Amsterdam, Oxford and New York, 1976.) Dfl.103; $39.75.

THE basic atmospheric engine operates between a source which is derived from solar radiation absorbed by the atmosphere, or by the surface, and a sink which is the emission of infrared radiation to space. Radiation processes are, therefore, of fundamental importance to atmospheric study. Further, because of the current concern about the global climate and possible mechanisms through which climate may change, there is a lot of interest in the Earth's radiation budget and the possibility of small alterations which might occur in it, due to changes in the radiation input or output. For instance, variations in the net solar input might occur either due to changes in the sun itself or changes in the atmospheric cloud or dust content; or variations in the emitted radiation from the atmosphere itself might occur for similar reasons.

There are few textbooks available on atmospheric radiative transfer. One of the best of the standard texts written by R. M. Goody in 1964 is now out of print, so that this new text by Paltridge and Platt is very much to be welcomed. It presents the fundamental theory of radiative transfer, and shows how empirical and theoretical approximations may be applied to the transfer of radiation in the clear atmosphere and in clouds. A lot of very useful up-to-date information is contained in the book about the radiative properties of the surface, of different types of clouds and aerosol, and about atmospheric transmission in different spectral regions. Emphasis is placed on radiative processes in the troposphere; little is said about the high atmosphere.

The book does not set out to be a thorough theoretical treatise. In fact, some of the theoretical presentation is confused (for instance, the presentation of the Curtis–Godson approximation in chapter 7 and its confusion with the pressure scaling of absorber amount). Rather, the book is aimed at providing the methods and means for meteorologists and atmospheric physicists who need to incorporate radiation processes into atmospheric models or work out simple practical atmospheric problems involving radiative transfer. For such people the book will be very valuable indeed and well worth purchasing. **J. T. Houghton**

J. T. Houghton is Professor in the Department of Atmospheric Physics at the Clarendon Laboratory, University of Oxford, UK.

The "only" techniques' journal for immunologists

Journal of Immunological Methods

Are you an immunologist in active research?
Are you using the following techniques in your laboratory?

Quantitating and detecting antibodies and/or antigens and haptens based on antigen antibody ineteractions
Fractionating and purifying immunoglobulins

WILEY INTERSCIENCE

FUNDAMENTALS OF ELECTROCHEMICAL ANALYSIS

by **Z. Galus,** *Department of Chemistry, University of Warsaw.* Translation editor: **G. F. Reynolds,** *The Research Laboratory of Instrument Physics, Reading University.*

This book provides a broad coverage of the theoretical principles of almost all methods used in electrochemical analysis. It also contains practical material for making and interpreting electrochemical measurements in analysis, research quality control or advanced study. It concentrates on polarography, stationary electrode voltammetry, chronopotentiometry and rotating disc electrode techniques, and includes cyclic voltage methods, the ring and disc electrode techniques, and most other electroanalytical methods. (Ellis Horwood series in Analytical Chemistry)

538 pages December 1976 $44.65/£23.50

Published by Ellis Horwood Ltd., Chichester, and distributed by John Wiley & Sons Ltd.

CRYOCHEMISTRY

by **M. Moskovits,** and **G. A. Ozin,** both of *University of Toronto.*

Introduces the fundamentals of cryochemistry, focusing on chemical aspects of the subject: synthesis, structure, and reactivity. Presents an up-to-date account of the technology available to the cryochemist and its application in diverse fields.

544 pages December 1976 $39.00/£25.05

PHOTOCHEMISTRY OF HETEROCYCLIC COMPOUNDS

edited by **O. Buchardt,** *University of Copenhagen.*

Essays by specialists in the subject survey the entire field of heterocyclic chemistry.

632 pages August 1976 $59.85/£34.90

MICROBIAL PRODUCTION OF NUCLEIC ACID-RELATED COMPOUNDS

edited by **K. Ogata,** *Kyoto University;* **S. Kinoshita,** *Kyowa Hakko Kogyo Co. Ltd;* **T. Tsunoda,** *Ajinomoto Co. Inc.,* and **K. Aida,** *Institute of Applied Microbiology, University of Tokyo.*

This book includes details of various newly established techniques for the industrial production of nucleotides, and of studies on the production of nucleic acid-related compounds.

366 pages November 1976 $30.00/£18.90

Published by Kodansha Ltd., and distributed by John Wiley & Sons Ltd.

TRACE ANALYSIS:
Spectroscopic Methods for Elements

edited by **J. D. Winefordner,** *University of Florida.*

A reference source that provides important information for those involved with trace analysis of elements in real samples. Analytical figures of merit including detection limits, sensitivities, selectivities, precisions, and accuracies are given where possible for each element by each atomic technique: only those techniques that are truly trace analytical methods are dealt with.

496 pages June 1976 $30.95/£19.10

PROGRESS IN INORGANIC CHEMISTRY
Vol. 21

edited by **S. J. Lippard,** *Columbia University.*

This volume of the series continues the authoritative forum for critical evaluations and comprehensive presentations of advanced knowledge in every area of the discipline.

304 pages April 1976 £15.00/$27.70

A New Quarterly Journal:

INTERNATIONAL JOURNAL OF ENERGY RESEARCH

The area of Energy research and development is faced with several obstacles. It is an important and rapidly expanding but broadly interdisciplinary field at a time of severe financial restraint. Its rapid expansion has meant a fragmentation of the literature and severe communication difficulties between workers. Frequently work of high utility and calibre receives less attention that its due partly because it does not reach a wide enough audience, either through the specific circulation of the journals used, or because there exists no suitable vehicle – *particularly in the case of scientific and technological research. The* **International Journal of Energy Research** aims to satisfy this need and provide an interdisciplinary platform for the results of energy research without the constraints imposed by aiming at a restricted audience. The subject matter of the journal will be concerned with the development and exploitation of both traditional and new fuels and other sources of energy, and an interdisciplinary approach to this interdisciplinary subject will be encouraged.

INTERNATIONAL JOURNAL OF ENERGY RESEARCH VOLUME 1 1977

(UK) **£22.50** per annum, Elsewhere US **$45.00** per annum.

Editorial Board:

North American fossil vertebrates

Athlon: Essays on Palaeontology in Honour of Lovis Shano Russell. Edited by C. S. Churcher. Pp. 286. (Royal Ontario Museum: Toronto, 1976.) $15.

THIS *Festschrift* volume honours Dr Lovis Russell, who recently retired as Professor of Geology at Toronto University and Chief Biologist at the Royal Ontario Museum. Nearly all the 16 scientific papers are therefore concerned with aspects of North American vertebrate palaeontology, and over half of them discuss vertebrate morphology and systematics. These papers include the following: Dineley, on the mode of life of the heterostracan fish *Ctenaspis*, which seems to have ploughed through the surface layers of sediment; Olson and Lammers on a labyrinthodont amphibian, which seems to be intermediate between the trimerorhachoids and the brachyopoids; Morris, on the hypsilophodont dinosaur *Thescelosaurus*, prefers Thulborn's classification of the group to Galton's; Green and J. E. Martin revise the didelphid marsupial *Peratherium* of the North American Oligocene and Miocene; Turnbull reconstructs the jaw musculature of the South American sabre-toothed marsupial *Thylacosmilus* and shows that the stabbing action was by the action of the hyper-developed ventral cervical musculature, the relative proportions of the jaw-closing muscles not being of specialised carnivore type; Turner and L. D. Martin describe two new rhinocerotoids from the Oligocene of Nebraska; Hooijer compares the pygmy mammoth of the offshore Californian Channel Islands with other dwarf elephants; Lundelius and Slaughter revise the taxonomy of North American Pleistocene tapirs; and A. E. Wood revises the taxonomy of the Oligocene rodent family Ischyromyridae. Finally, at a somewhat higher phyletic level, Carroll redescribes the South African late Permian younginid genus *Heleosaurus*, which shows many similarities to the little early Triassic archosaur *Euparkeria*. He concludes that younginids may be ancestral to the archosaurs, and that the larger early Triassic archosaurs may represent an early divergent specialisation for a semi-aquatic habitat.

Five of the papers are faunal studies. Madeleine Fritz describes an unusual specimen made up of a series of overgrowths of two ectoproct species on a stromatoporoid base. Holman describes Cenezoic herpetofaunas from Saskatchewan and shows that, although the amphibian fauna of the early Oligocene was already essentially modern, the reptile fauna only became modernised between then and the late Miocene. Wann Langston suggests that the late Cretaceous Scabby Butte fauna was preserved in a marshier environment that lay closer to the sea than the more varied dinosaur faunas of the Edmonton and Oldman deposits. Storer shows that the Hand Hills Formation of Alberta contains both Mio-Pliocene mammals and Pleistocene mammals, the deposit resulting from glacial reworking and mixing. Finally, Hibbard shows that a stratigraphic confusion between three volcanic ash deposits in Kansas has led to the incorrect placing of the Cudahy Pleistocene fauna in the Yarmouthian instead of the Late Kansan.

In the most general (and therefore most generally interesting) paper, Sloan discusses the ecology of dinosaur extinction in western North America as shown by the replacement of the dinosaur-dominated *Triceratops* fauna by the mammal-dominated *Protungulatum–Stygimys* fauna that probably immigrated from Asia. He concludes that there is now good evidence of a major floral change at this time, there being a 45% drop in floral diversity and a 71% loss of plant taxa by extinction over 1–2 Myr. This change from a subtropical angiosperm-based flora to a cooler, temperate, more conifer-dominated flora was, Sloan suggests, due to climatic changes resulting from the retreat of the North American inland sea from the region.

Most of the papers are above-average in interest, the book is well produced and edited, and there are relatively few typographical errors. Even at prevailing rates of exchange, it is not expensive. As with any such collection, the main problem is that most workers will find that, however good the papers are, only a small proportion are relevant to their particular range of interests.

Barry Cox

Barry Cox is Professor of Zoology at King's College, University of London, UK.

Developmental biology

Explorations in Developmental Biology. By C. Fulton and A. O. Klein. Pp. xv+704. (Harvard University: Cambridge, Massachusetts, 1976.) £11.90.

THE authors of this book state that it is unsatisfactory to teach developmental biology through "formal presentation of a body of knowledge to be passively assimilated by students from books and lectures", and claim a novel approach in providing a collection of original papers, grouped in topics and linked by passages which clarify details, provide questions and suggest further reading. There are 59 papers, giving very broad coverage and dating from Spemann and Mangold (1924); but most of them are post-1960. Despite their praise of original papers and scorn for textbooks, the authors provide two text-type chapters (on amphibian embryology and cells in culture), abridge several papers and give an extract from Twitty's delightful *Of Scientists and Salamanders* rather than the original work.

Do any University teachers instruct in the way criticised by Fulton and Klein? The problem lies in balance. Since research papers are often difficult and time consuming to read critically, it is at least efficient to teach mainly by lectures and texts to elementary students, but to swing later to original sources, when the teacher's role becomes to select reading, help in discussion and provide factual background. The book duplicates this role and, of course, cannot keep up with the latest information as the teacher can.

A good textbook is not an *ex cathedra* statement of the truth. It stimulates by telling what is known, what is uncertain about what is known, what is unknown and how it might come to be known. As a summary of our knowledge, it can cover immense breadth, and at least mention the oddities. A comparison illustrates this. Fulton and Klein take 63 pages to discuss whether the statement that "genes do not change during embryonic development" is a "cornerstone of developmental biology" or a reasonable working hypothesis. Ebert and Sussex's *Interacting Systems in Development* covers the ground in 5 pages and asks more probing questions. So does Berrill's *Developmental Biology*, and adds the unusual case of *Ascaris*. Fulton and Klein make a hardly fair comparison with a brief and misleading paragraph in an introductory general biology text.

Would anyone find the book useful? Probably not those with access to an adequate library, teaching special aspects in tandem with a team of colleagues. For the teacher struggling to cover the field alone, it may prove a godsend. But a warning: in the areas I know best, the choice of papers and some of the linking commentary is idiosyncratic. This is of course the point about University teaching. It is done by individuals whose choice of emphasis provides an essential diversity. Fulton and Klein's course sounds fun, but it isn't mine. **J. R. Downie**

Dr Downie is a Lecturer in Zoology at the University of Glasgow, UK.

Metabolism in filamentous fungi

The Filamentous Fungi. Vol. 2: Biosynthesis and Metabolism. Edited by John E. Smith and David R. Berry. Pp. xiv+520. (Arnold: London, June 1976.) £19.75.

Much of the space allocated to this review could be taken up by listing the twenty-two authors and the seventeen chapters which they have contributed to this, the second volume of a series on the filamentous fungi. The writers endeavour to cover all aspects of biosynthesis of carbohydrates, lipids, fatty acids, nucleic acids and proteins and the associated pathways of intermediary metabolism and nutrient assimilation.

The authors, in their attempts to succeed in this, are forced to produce highly condensed articles some of which, although they may be comprehensive, are very hard work to read. Many authors, however, do set out to make their contributions readable and comprehensible to those not working directly in their own field. A. T. Bull and M. E. Bushell begin by providing a good introduction to the problems encountered in the construction and operation of continuous flow fermenter systems for filamentous fungi.

A. H. Rose provides an excellent account of the clinical nature of membrane components. At the other end of the spectrum, one or two authors make few concessions to anyone who is not fully conversant with the terminology and techniques used in their discipline, and consequently have produced chapters which are very difficult to digest.

The latter is not consistent with the editors' intent to include undergraduate and postgraduate students in the readership. Although perhaps not all subjects would have been amenable to this treatment, it would have been useful if the editors had encouraged authors to begin their chapters with a brief introduction to the nomenclature. For example, the chapter on Carotenoids by T. W. Goodwin begins with a good introduction which rapidly accelerates to a detailed exposition with which the reader can keep in step.

An encouraging feature of this book is that a number of chapters conclude with suggestions for useful future developments, whereas volumes presenting up-to-date reviews often leave one with the feeling that most worthwhile work has been done or is in hand. V. W. Cochrane, in the closing paragraphs of his chapter on glycolysis, encourages workers in the field to investigate *Neurospora crassa* in the same detail with which bacteriologists have studied *Escherichia coli* and also points out that some groups of fungi have been largely neglected. In another instance, J. A. Pateman and J. R. Kinghorn have attempted to present their review of nitrogen metabolism in such a way as "to allow deeper study for those interested in a particular field".

This is a valuable volume as it provides a good review of present knowledge, with copious references, and it may well have the effect of encouraging others to investigate some of the neglected areas of the subject.

H. A. S. Epton

Dr Epton is a Lecturer in Botany at the University of Manchester, UK.

Numerate account of marine ecology

The Ecology of the Seas. Edited by D. H. Cushing and J. J. Walsh. Pp.x+467. (Blackwell: London and Oxford, 1976.) £8.75.

The names of Cushing, Dugdale, Kelley, Parsons, Steele and Walsh, to mention but 6 of the 14 contributors, should be sufficient to promise good value in this book for marine ecologists. I have no doubt that it is good value, and to be highly recommended.

What these very numerate ecologists aimed to do, under the leadership of Cushing and Walsh, was to set out "the present state of knowledge of the quantitative nature of marine ecosystems": in 6 parts, comprising 16 chapters, with very adequate references and indexes (authors, subjects, species and geographical). They proceed systematically from the characteristics of the seas and the life they maintain, through the forms and functions of marine ecosystems, with some of the consequences in terms of evolution, and of yield for man. The final section is in two parts: the first, an excellent chapter on sampling (by J. C. Kelley), and the second concerning a comprehensive "simulation model" of ecological relationships at three trophic levels, within the upwelling systems off Peru, Baya California and north-west Africa.

In all this, prime emphasis is on the processes concerned, both hydrodynamic and biological: indeed, life *in* the sea. In association there is emphasis on the absolute necessity for distinguishing between variability in space and variability in time, which variations have been "confounded" in more senses than one for most aspiring marine ecologists over the past 50 years.

I cannot but be impressed by the way in which so many of the problems —which could be seen only dimly 50 years ago and, although perhaps perceived a little more clearly 25 years ago, still left marine ecologists gravelled for lack of both data and technique—are now (following great developments in both) beginning to yield understanding, and even the possibility of prediction, in such complicated circumstances. That the methodology is far from simple, and the options many, is further illustrated by a quotation from the last chapter, by Walsh (references omitted): "Depending on the problem, one must decide whether steady state or time dependent studies . . . with simulation and/or statistical models . . . involving the analytical or numerical solution . . . of differential or difference equations . . . made of linear or non-linear terms . . . should be solved on analog or digital computers . . . in relation to spatial or single point considerations . . . and exogenous or endogenous driving functions . . . within a stochastic or deterministic parameter space . . .".

As Cushing says in his preface, the contributors are writing as scientists, who have spent long periods at sea, for scientists who are beginning to work at sea. I find it difficult therefore, to think of a better or more challenging introduction. Whether this important science will, however, be able to expand in foreseeable circumstances, in the manner that progress made so far seems to justify, is uncertain to say the least. Quite apart from never-ending arguments about the Law of the Sea, it is inherently very costly, if only in terms of ships and resources required for the extensive synoptic surveys that better understanding demands. For this reason alone, one of the most important points made by Walsh concerns the present challenge to devise new methods of exploiting existing data banks, rather than heedlessly adding to them!

One last point: taking into account the high price and unattractive binding, it is difficult to understand why the publishers let the team get away with duplicating Fig. 7.6 by the identical (except for the legend) Fig. 8.2.

C. E. Lucas

Sir Cyril Lucas was formerly Director of the Marine Laboratory, Aberdeen (retired 1970) and subsequently a member of the Natural Environment Research Council, UK.

announcements

Awards

Alfred Champagnat (France) is the winner of the 1976 Unesco Science Prize, and **Louis Estrada Martinez** (Mexico) and **José Reis** (Brazil) will share the 1974 Kalinga Prize for the popularisation of science.

A prize of DM 10.000 is donated by Boehringer, Mannheim, every two years for outstanding work in the field of biochemical instrumentation and analysis. One or several papers concerning one theme, either published or accepted for publication between October 1, 1975, and September 30, 1977 should be sent to: Prof. Dr I. Trautschold, Medizinische Hochschule Hannover, 3000 Hannover 61, Karl-Wiechert-Allee 9.

The Science Research Council intends to award about fifteen fellowships in 1977 under its new **Advanced Fellowship Scheme.** These fellowships fill the gap between SRC postdoctoral and senior fellowships schemes. They will be awarded to outstanding young workers who have already proved their ability but have not yet obtained a tenured post. The Fellows would have no guarantee of a tenured post on completion of their fellowship although most would be expected to gain such posts in due course. The stipend will be linked to the University lecturer scale. Details of the regulations are available from the Science Research Council, State House, High Holborn, London, WC1. Applications for advanced fellowships to commence on October 1, 1977 should be sent to the Science Research Council by January 31, 1977.

Appointments

Members of the **Genetic Manipulation Advisory Group** have been announced by the Secretary of State for Education and Science. They are Sir Gordon Wolstenholme (Chairman), J. B. Brooksby, K R Dumbell, H. J. Evans, J A. Gilbey, R. J. C. Harris, M. Jahoda, Bernard Langley, J. E Lawrie, John Maddox, K. Mather, J. Ravetz, M H Richmond, J. H. Subak-Sharpe, Sir Brian Windeyer. Further appointments are expected shortly.

Michael John Bevis, Reader in Metallurgy and Materials Science at Liverpool University, has been appointed to the newly created Chair in Non-Metallic Materials at Brunel University. Professor Bevis will become Head of the Department formerly called Polymer Science and Technology.

F. John Bryant of the Department of Physics, Hull, has been appointed to a Personal Professorship.

Person to Person

The possibility exists of arranging postdoctoral research in investigations of the kinetics of chemical reactions relevant to terrestrial and planetary environments. Topics currently under study include the kinetics of the formation, decomposition, and photodissociation of mesospheric cluster ions, and the mechanisms of production of interstellar molecules. Informal enquiries should be addressed to R. R. Burke, CRPE, CNET & CNRS, 45045 Orléans Cedex, France.

Echange culturelle. Famille Américaine désire envoyer fils, 17 ans, pour vivre en famille pour une année en France ou en Belgique. En echange nous prendrions le fils ou la fille de la famille hôte et nous l'éleverions comme le nôtre pour une année Date préférée pour commencer· Juin 1977 (James F. Quinlan, Box 8, Mammoth Cave, Kentucky 42259, United States).

There will be no charge for this service. Send items (not more than 60 words) to Marcus Dobbs at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries We reserve the right to decline material submitted No commercial transactions

newly on the market

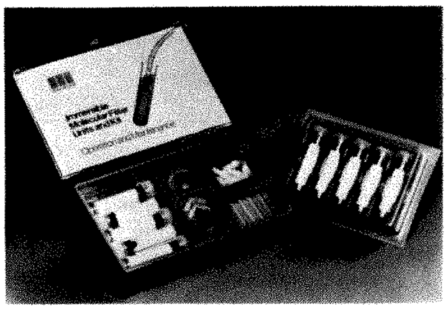
These descriptions are prepared by the staff of *Nature* on the basis of material provided by manufacturers. There is a Reader Enquiry Form on the page facing the inside back cover.

Automated X-ray powder diffractometer. Philips. The APD 10 comprises a Philips 3 kW generator with vertical goniometer equipped with graphite monochromator and 35-sample changer, plus associated controls and chart recorder; the additional automation facilities are controlled by a minicomputer using plain language instructions *via* a teletypewriter. A dual station cassette unit enables measurement data to be collected for off-line processing on a larger computer. Standard programs are available. The APD 10 enables routine work to be done overnight or at weekends. Applications cover geology, mining, steel production, petro-chemicals, paint and air pollution.
Circle No. 43 on Reader Enquiry Form

Double beam atomic absorption spectrophotometer. Pye Unicam Ltd. The SP2900 has both peak height and peak area measurement which can be remotely initiated. The timing for peak height measurement is from 0–99.9 seconds in 100 msecond steps and peak area integration is over a 4 or 10 second period. The built-in lamp turret keeps four pre-focussed lamps aligned, powered and ready to work. Lamp selection is optical. The SP2900 has aircraft-style, 7-bar, bi-polar illuminated digits. The range is −0.05 to 1.999A with a switchable decimal point and double over-range indication. Readout is in absorbance, concentration or emission units and digital update is 2.5× every second. A concentration calculator helps produce fast and accurate results with a single operation of curvator and scale expansion controls using just two standard solutions. The single curvature control is independent, wide-ranging and does not affect zero. Calibrated scale expansion is from 0.2× to 50× (analogue and digital). The background correction accessory provides automatic, simultaneous correction for high background absorbances—particularly important when using electro-thermal atomisation techniques. The SP2900 corrects for 1.5A of background to better than 1%.
Circle No. 44 on Reader Enquiry Form

Linear displacement monitor. Rofin Ltd. High resolution dual or single axis light spot position sensing system includes one- or two-axis position resolution to 0.0001 inch, independent of zero and sensitivity control for each axis, analogue output with frequency response to 3KHz and position sensitivity independent of light spot size when used with a Helium-Neon or other visible C.W. laser. Position sensitivity is dependent on the detector type used, incident light power and the sensitivity setting. Applications include: flatness . . . positioned over a surface, the monitor gives a meter indication of the deviation from flatness at any point; auto-collimating . . . using spherically corrected lenses, the displacement display can measure pitch and roll angles; motion monitoring . . . with the high frequency analogue output and linearity of output, the monitor can measure vibration rate and amplitude.
Circle No. 45 on Reader Enquiry Form

Immersible molecular separator. Millipore. Sized to handle volumes between 1 and 100 ml, the separator is ideal for concentrating proteins, viruses and colloids, removing salts, buffers and solvents, deproteinising samples and separating unbound ligands. The unit can be reused after a simple cleaning operation. The device is lowered into the solution to be processed and is then connected to any convenient vacuum source. Filtrate passes through the membrane into the core, and then flows via the vacuum line to a suitable trap. Retained molecules (the retentate) remain in the original sample container. Both the retentate and the filtrate fractions can be recovered. Filtration can be automatically terminated at any preselected point.
Circle No. 46 on Reader Enquiry Form



Immersible molecular separator

Amino acid analyser. Mark Instrument Company. The newly-developed system provides single column analysis for protein hydrolyzates and physiological fluids. The Model AAA-F-100 Amino Acid Analyser eliminates lengthy and laborious manual analyses and affords the following benefits: complete and permanent strip chart presentation of the amino-acid constituents of the sample, the quantity and sequence of their elution from analyser's ion exchange column; only a minute sample is required; more accurate data and reproducible results; flexibility through easy modification, addition of accessories, or variations in operational conditions; table top size.
Circle No. 47 on Reader Enquiry Form

Multi-point recording facility. Chandos. A new electronic attachment provides multi-point recording facilities from a single channel recorder. Two or more of these units could be used with existing dual channel or multi-channel recorders if they are continuous trace. The system provides a channel identification datum and a means of adjusting the time spent recording individual points. Models accommodating up to 36 points are available for various types of measurement—pressure, temperature, pH, conductivity, oxygen, selective ions etc. Adjustment and zero suppression can be built in to provide a given full scale deflection.
Circle No. 48 on Reader Enquiry Form

Miniature accelerometer. SE Labs. The EGAL 125-5, measures acceleration, vibration and shock from 0.001g to 5g. Weighing less than 0.5 g and occupying less than 0.006 cubic inches, the EGAL is ideal for situations requiring minimal weight addition to the item under test. Applications vary from tremor studies on human and animal subjects to vibration and flutter analysis on vehicle models undergoing wind tunnel tests. The EGAL is a semiconductor strain gauge device which measures static and dynamic acceleration with a sensitivity of 15mV/g unamplified. Available with six different mounting facilities, it has an operational temperature range of −40 to 121 °C. In addition, it is available with a 0.7 critical damping option.

Catch 22

We don't often comment editorially on the stories of Soviet policy towards dissidents that we carry with monotonous regularity. This is not because we don't believe them—it's because they have a peculiar eloquence of their own to which cosy editorialising from a London office can add little. Sufficient it is that scientists should be aware on a worldwide basis of what goes on and act accordingly. The same goes for the testimony of Vladimir Bukovskii on the following page. But one story emerging from Moscow so confounded our sense of logic that we feel it deserves a little comment.

Academician Veniamin Levich was briefly taken into custody on December 21 as part of a new campaign against participation in the unofficial scientific seminars for dismissed scientists. He was referred to a TASS statement of November 9 concerning the Soviet position on emigration. Since this provoked no overseas reactions, he was told, this must imply tacit agreement.

The unattributed statement, one of many issued on or around Revolution Day, was broadcast in English at 07.36 and ran, in part, "each request from an individual citizen to be allowed to go and live in another country in order to reunite split families is given full consideration. Refusals are made in an insignificant number of cases, when the citizen expressing the wish to leave the USSR has had access in the course of his duties to works or information that represent a state secret . . ."

Since "the secrets of a state are always its own exclusive property", it went on, "it is an internal question for the Soviet Union to decide which specific works or information are to be considered secret, obsolete, or to have lost importance in guaranteeing the defences and other important national interests of the USSR". Accordingly, "any attempt at pressuring competent Soviet organisations into changing their position is considered an interference in the domestic affairs of the USSR. As for the big anti-Soviet noise raised in the West, it pursues the sole aim of misleading public opinion . . . Bourgeois propaganda is doing everything it can to distract attention from the systematic and gross violations of basic human rights in capitalist society".

In view of the strong hints that a big anti-Soviet noise is an interference in the domestic affairs of the USSR it is somewhat remarkable that the said "competent Soviet authorities" now quote the lack of "noise raised in the West" as a justification for their policy. ☐

No export potential in steam tape-recorders

"Parlez-vous electric?", runs a recent large advertisement by the UK Electricity Council in national newspapers, at a cost of goodness-knows-how-many-thousand pounds. "There are thousands of tape-recorders with headsets in use in UK schools. Thousands more are used each year by executives of multi-national companies on six-week intensive courses in a foreign language. Headsets. Video tape-recording equipment. Magnetic tape. All these modern educational aids are powered by electricity. The child learns his language idiomatically. So do the men. Men responsible for earning this country millions of pounds in export orders from foreign countries. Exports are this country's life blood. Electricity helps generate them. **Think Electric**".

"Look here, Blenkinsop," said the Minister for Energy, the moment the Director of the Electric Power Generating Board had sat down. Blenkinsop knew immediately that this was to be the dreaded eyeball-to-eyeball confrontation. He fumbled for his pipe. "I'm getting fed up with the way everyone else in the Cabinet is talking about export, export all the time—boasting about their departments' achievements—and we're still importing in our department. I get a lot of stick for it, so you'd better get your advertising copywriters to do something about brushing up our image. There must be something we export. Oh, and also", Blenkinsop shifted uneasily, "I've been looking at electric consumption figures for these last few weeks. What's going on? We're 5% down on last year, and I've got all these boilermakers, miners, nuclear engineers and what-have-you on my back about building more power stations. I want you to get out and stimulate consumption in a really big way. Find something which really soaks up electricity and push it hard." "Yes, sir" said Blenkinsop. The minister pulled a drawer open. Blenkinsop wondered if it was to be a letter asking for his resignation. But no; the minister decanted three or four small boxes on the table.

"Know what these are?" "No, sir". "Really, Blenkinsop, you're not very alert to the opposition. They are tape recorders—but they don't run on electricity. This is a clockwork one—it punches a tiny paper tape. It's made in Switzerland by all those watchmakers put out of business by digital watches. It sounds a bit like a 78-record, I admit, but you see how they'll develop it. This one's made in France. It runs on lighter-fuel, and I hardly need remind you that North Sea oil doesn't yield lighter-fuel so it'll have to be imported. And this one is made by our own dear old Gas Board; that's a shot across your bows, isn't it, Blenkinsop? Now you get people cracking; they've three big campaigns to do on export, consumption and competition".

"Yes, sir", said Blenkinsop, as his civil-servant brain swung into action "but, sir, if I can save us money with some sort of integrated campaign, do you thing I might, er . . . er . . . be so bold as to have a Permanent Secretary's 10′ 9″ × 7′ 3″ thick-pile carpet for my office? I only really qualify for the Deputy Secretary's 8′ 3″ × 6′ 4″ rug".

"Oh, very well" said the minister, irritably, and out trooped a gleeful Blenkinsop. "Odd people, these civil servants," mused the minister, "I wonder what he meant by an integrated approach . . . I hope he doesn't make a fool of us". ☐

The Bukovskii perspective

Vladimir Bukovskii, the dissident Soviet biologist released after years in and out of prison and psychiatric hospitals, answers questions from Vera Rich

VR : Do you think that your work in science, studying biology, in any way led you to the protest movement?

VB : I began to take part in the protest movement before I became a student. But my interest in the biological sciences and my studies helped. Science in the USSR (I don't mean the 'social sciences') has followed a path from being completely ideological to being partially so. It is said that at one time mathematicians were forced to prove the class nature of the integral. I did not belong to that period. In my time the physical sciences were already treated with great honour because of their defence potential.

Biology was far less lucky in this respect. Even in 1960, when I entered university, the father of Soviet biology was still Lysenko; genetics and biocybernetics were only just beginning to defend their right to exist. The very methodology of higher education; the abundance of unnecessary Party discipline; the barrack-like spirit; the dependence and the lack of rights of the students, who were blackmailed into joining the Komsomol and informing on their comrades by the threat of losing their grant and expulsion from the university . . . When I, at last, was expelled for "failure to conform with the character of a Soviet student" (for taking part in youth meetings on Mayakovskii Square), I was simply glad, to tell the truth. But my interest in biology remained, and later, even in prison, I continued my self-education as far as possible.

Under the influence of biology and while I was still at school my first disagreement with the ruling doctrine arose. The cornerstone of Marxism, the slogan "Being determines consciousness", evoked active protest in me. Society appeared to me as a living organism, and social consciousness, being the sum of individual consciousness, was the determinant of social processes. This incompatibility gave a stimulus to the analysis, criticism, and rejection of Marxism. Later the very fact of working with science, which develops in a person a careful concern with the truth, a discipline in thought and a training in patience, completed this process. It is not by chance that later there was wide participation of mathematicians, physicists and biologists in our movement. The scientific approach to legal questions, which was established in the first place by mathematician Aleksand Vol'pin, exerted an enormous influence on the whole development of our movement.

VR : How do you see your own case in the context of the aims of the Sakharov Human Rights Committee?

VB : I consider that the activity of the Sakharov Human Rights Committee in Moscow is a continuation of the process of scientific consideration of the problems of rights and injustices in the Soviet Union about which I have just been speaking. This process, in my opinion, belongs to the man of the future if he, like Andrei Dmitrievich Sakharov, will conscientiously, magnanimously and readily unite to defend all those who are being prosecuted. Like all my comrades in prison, I have always known that Sakharov remembers us, is concerned for us, and defends all of us. In the Vladimir prison we came to know that Sakharov had enumerated dozens of names of political prisoners in his Nobel lecture. For me personally it is clear that the activity of Sakharov and his Human Rights Committee was one of the origins of the wide international campaign for my release.

VR : Taking into account the existence of psychiatric persecution, what do you think is the proper position for Western psychiatrists? Should they boycott all contacts with the Soviet Union? Should they continue to take part in conferences in the Soviet Union, in the hope of exerting unofficial pressure on Soviet psychiatrists? Should the Soviet psychiatric profession be excluded from participation in international conferences until there is a change of policy towards dissidents?

VB : I consider the generalisation "the Soviet psychiatric profession" is not justified in all respects. There are different schools, currents and types of psychiatrists. It is almost impossible to speak of some single policy adopted by all psychiatrists towards dissidents.

In the last examination at the Serbskii Institute in autumn 1971, when, under public pressure, the authorities included among the experts several honest scientists such as Professor Melekhov and Professor Lukomskii, I had no questions regarding the profession's policy towards 'dissidents'. I did not doubt for a second that their decision would be objective.

In 1965 when, on the orders of the KGB, I was taken by force to City Psychiatric Hospital No. 13 in Moscow, young and completely unknown psychiatrists did not fear to declare me to be sane. Even in psychiatric prisons I met a few decent psychiatrists. Decency in these conditions amounts to heroism. Are you asking me whether I want to exclude these people from the world psychiatric profession, to break off their scientific contacts with you, or yours with them?

On the other hand, is it right to sit down at the same table with Lunts and Snezhevskii, hoping to exert 'unofficial pressure' on them? Their mere presence at the same table as Western psychiatrists gives them respectability, introduces them into the ranks of psychiatrists and makes you accessories to their crimes. By no pressure can you return to them their long-lost consciences. The very idea of behind-the-scenes deals with murderers and executioners is incompatible with the conscience of a true scientist. The 'diplomatisation' of psychiatry has already led to a number of cowardly compromises: contacts between western psychiatrists and odious figures of Soviet psychiatry, and the refusal to discuss openly and to condemn Soviet psychiatric malpractices. It must be understood that the Soviet authorities consider such behaviour to be proof of the West's weakness which only strengthens the repression. It is also very convenient for those in the West who are prepared to have contacts with the Soviet Union at any price.

Is it not remarkable, then, that people educated in the traditions of Western democracy, and accustomed to expressing their opinions vigorously and to considering honour in their relationships with each other, should think it is possible and necessary to conspire, scheme and even compromise their consciences, provided contacts with the Soviet Union are involved? Yet it is not only tactically more correct, humanly speaking it is easier to maintain the direct honourable position of a scientist. One does not have to force one's conscience. No one ever has to sit down at the same table with those known to take part in psychiatric repression. In any case it is necessary in the course of discussions and resolutions at any international meeting to speak openly to Soviet psychiatrists, saying all you think about the repression, and thus to extend the hand of help to the honest scientists who stand bashfully behind their dishonest colleagues. It is necessary to expand the participation of Western psychiatrists in the struggle for each victim of psychiatric repression. Only in this way, without and within, can one help cure Soviet psychiatry and establish in it such people as my comrade in prison, Semeon Gluzman. □

No season to be jolly

David Spurgeon reports from Ottawa on recent nuclear developments in Canada

CANADA'S nuclear programme has been in something of a turmoil lately. Certainly for officials of Atomic Energy of Canada Ltd. (AECL), the Crown corporation charged with nuclear R&D, exports and technical aid, the season has definitely not been jolly—quite the reverse. The opponents of nuclear power have stepped up their attacks in public, in AECL's eyes sometimes quite unfairly. The auditor-general has questioned their accounts. And that has led the House of Commons' Public Accounts Committee to investigate what looked like highly unusual and extraordinarily large payments to agents in such unlikely places as Panama and Liechtenstein; these had apparently been made as commissions on CANDU reactor sales to countries like Korea and Argentina, which many thought should never have been sold reactors at all.

The auditor-general's report then added insult to injury by revealing that AECL lost $100 million on one of these deals, though it was later disclosed that this loss could be reduced to $25 million by yet another sale now being negotiated with the same country, Argentina. It was shortly after all this appeared in front-page newspaper headlines that the Minister of External Affairs, Mr Donald Jamieson, announced a new nuclear export policy which because of its stringent requirements for safeguards will probably restrict overseas sales of reactors in the future.

This was less a direct result of the foregoing events, however, than a product of India's detonation of a nuclear device in May, 1973, with the help of a Canadian research reactor. But it has already had a paradoxical effect: since Pakistan would not agree to the terms of the new policy, Canada's nuclear aid programme with that country will be cut off, in spite of the earlier contention of the Prime Minster, Mr Trudeau, that Canada should not withhold nuclear technology from developing countries. Mr Jamieson has admitted to the press that there is a real possibility that the nuclear policy decision will cause electrical brownouts in Karachi.

To some people, all this seems to strengthen the suggestion made not long ago by John Shepherd, executive director of the Science Council of Canada, that AECL should give up its export sales programme of CANDU reactors and concentrate on exploiting what could be a huge domestic market. To do this properly, he proposed that AECL should revert to its R&D function and help form a consortium with private nuclear industry and the provincial power companies.

Long and complicated

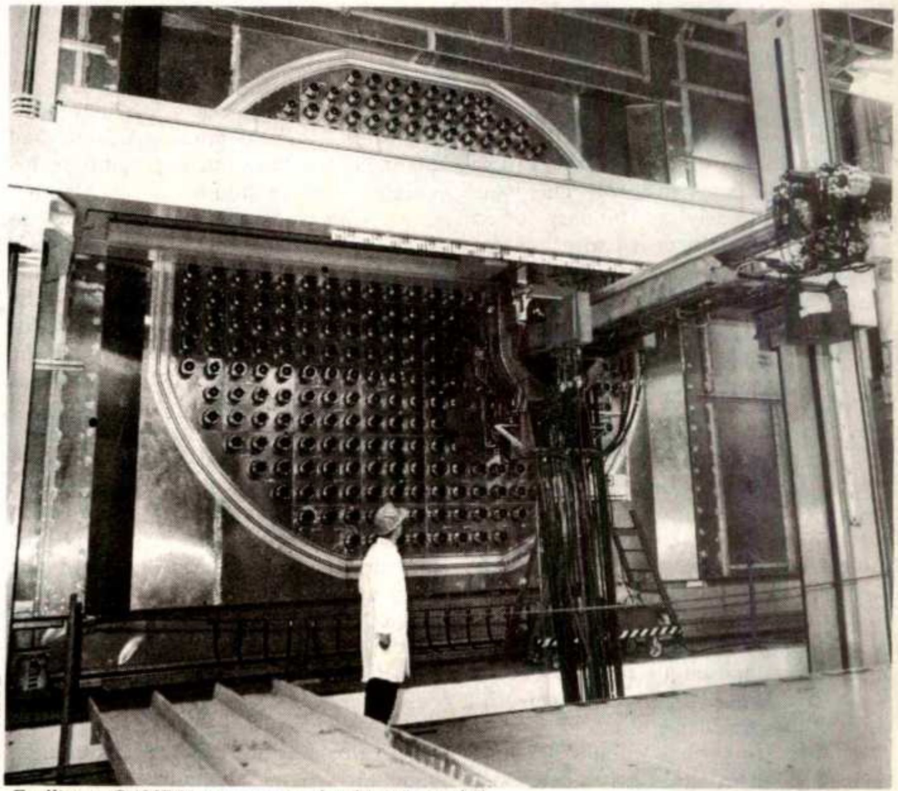
The story of the commissions on CANDU sales is a long and complicated one not yet revealed in its entirety to the Canadian public. One commission, on the Korean sale, amounted to $18.5 million. The company involved, United Development Inc. (UDI), reported that it paid $1.3 million of this to the Triangular Trading Company of Panama as a portion of the $8.1 million it claimed for expenses in the deal.

UDI, whose headquarters are also listed as being in Panama, also paid fees totalling more than $1 million to firms in Hong Kong and Frankfurt for technical and economic studies of CANDU compared with other nuclear systems. AECL agreed to pay the fees after it had renegotiated the agent's contract and reduced the commission from about 5% to 1%, plus documented expenses.

UDI is headed by Shaul Eisenberg of Tel Aviv, and it was the inadequate documentation for the $8.1 million expense account paid to him that prompted the auditor-general, J. J. Macdonell, to report it to parliament. Mr Macdonell made it clear that AECL officials tried to persuade him not to make the matter public, and AECL's chairman, Ross Campbell, admitted this but said he was concerned not about the facts but about the innuendos that would damage AECL's reputation and those of the companies it dealt with. In fact, a special study of AECL's financial management on behalf of the auditor-general was strongly critical of its overall handling of expenditures. This study, unrelated to the Korean sale, was part of a continuing review of Crown corporation's management.

The second commission case involved a joint sale by AECL and Italimpianti of a CANDU reactor to Argentina. The Italian firm obtained an agent for this sale and then asked the Canadian government to pay half the cost. Canada responded by having $2.4 million deposited into a Swiss bank account held by a trading firm in Liechtenstein, as requested, but never learned the name of the agent or whether it was the Liechtenstein firm.

The Italian firm stalled on providing the answer, moving the Canadian Energy Minister, Alastair Gillespie, to wonder publicly if "there may be Canadians involved." He said the Royal Canadian Mounted Police had been asked to find out who received the $2.4 million, if they could.



AECL

Fuelling a CANDU reactor: no shutdown is needed

Exports restricted

The new nuclear policy announced by Mr Jamieson just before Christmas means that Canada will restrict its exports of nuclear equipment and materials to countries that either have signed and ratified the Nuclear Non-Proliferation Treaty or have "full-scope" nuclear safeguards. In addition, these countries will have to accept the kinds of additional bilateral safeguards announced by Canada two years ago. The alternative to adherence to the NPT means that a country must accept equivalent international safeguards on its complete nuclear programme (outside military aspects if it has nuclear weapons already). This is what Pakistan refused to do.

Announcing the policy at a press conference, Mr Jamieson claimed that Canada now has the toughest requirements imposed by any nation supplying nuclear materials. He said Canada decided on the policy only after it had failed to persuade other members of the so-called London Club to take similar steps together. Canada now hopes that these other nuclear-supplying countries will follow its lead, which is designed to prevent the proliferation of nuclear weapons. And he suggested that recent tightening of policies by the United States and France was a hopeful sign.

Canada's new policy is seen also as a reinforcement of a safeguards policy announced two years ago, which some uranium customers have not been observing closely. A number of countries, including Japan, Switzerland and the EEC countries, have not yet completed all the required safeguards. After allowing two six-month extensions of supplies, the Canadian government has announced that it will cease uranium shipments at the end of December, 1977, to force compliance with the policy. Mr Jamieson said he hoped that by that time the safeguards would be in place and supplies could continue uninterrupted.

In notes distributed before his press conference, Mr Jamieson said:

> Nuclear export policy already requires binding assurances that what Canada provides will not be used for explosive purposes. Existing policy, however, does not cover what a country receives from other suppliers or what it might do on its own. The new policy will close this gap. We will have, therefore, assurance by treaty that Canada's nuclear customers will have been selected from amongst those countries which have made a clear and unequivocal commitment to the non-proliferation of nuclear weapons.

Mr Jamieson added that Canada recognises the legitimate energy requirements of its trading partners, but is determined to do all it can to avoid contributing to nuclear weapons proliferation. It was for that reason that Canada had unilaterally decided to strengthen further her safeguards requirements. As in the past, "We are prepared to accept the commercial consequences of being clearly ahead of other suppliers. This is the price we are prepared to pay to curb the threat to mankind of nuclear proliferation." □

Canadian High Commission

Don Jamieson, External Affairs Minister

Holland's nuclear problems

Casper Schuuring reviews a troubled year for nuclear power in the Netherlands

IF it had not been so before, nuclear energy became a major political topic in the Netherlands in 1976. The issue was alive as early as January when debates on the subject led to a government decision to postpone definite planning for three 1,000 MW nuclear power plants until after the next elections in May 1977. The Netherlands already has two existing smaller plants, of 447 MW and 54 MW.

Overcapacity in generating power and uncertainties regarding the nuclear fuel cycle were among the main reasons for the move, but political factors were important too. The small Radical Party (PPR), which takes part in the country's coalition government with Labour and Christian Democrats, has two ministers and an under-minister very much opposed to nuclear energy —one of whom is Fokele Trip, the Minister for Science Policy.

Labour, too, has doubts about nuclear power. The Christian Democrats are less perplexed. One of their ministers, for Economic Affairs, had planned the three nuclear plants in his energy memorandum of September 1974. Construction of the first was to start in 1976. Following the government decision to postpone the building of the plants, a declaration signed by 1,200 scientists covering a range of disciplines expressed their concern at the rapid expansion proposed for nuclear energy—as 2,300 colleagues of theirs had done earlier in the United States. Published at the end of January and originally addressed to the government, the declaration was then directed to parliament, which was to discuss the memorandum in February. With the decision on additional nuclear plants pushed to the next government, however, the parliamentary discussions lacked excitement.

Calm doesn't last

The calm was not to last. A conflict soon arose over a credit guarantee to be given by the government for the building and selling of components for two power plants in South Africa. The work was to be done by a group of industries participating in a consortium together with American and Swiss industries. The government had already indicated in mid-1975 that an export licence would be given, but in parliament a vote of censure was just passed covering exports of nuclear material and equipment to countries that had not signed the nuclear Non-Proliferation Treaty. South Africa is such a country.

The consortium was originally to have built two reactor vessels; but with a change in arrangements the vessels were to be built by General Electric and the Dutch industries could still take part in the work, for which only an export guarantee was then necessary. Discussion went on so long that at the end of May the deadline passed and a French consortium won the South African order. The Dutch government itself just survived a long and critical period, and relations between government and industry sustained a good deal of damage.

During the summer the Steering Group for Energy Research issued its second report. This concluded that conservation of energy should form a considerable part of Dutch policy, and offered two scenarios for energy use over the next 25 years. One involved a continuing growth of 4½% until the year 2000, and the other a levelling off to zero growth around 1995. The latter scenario, which the Group itself backed, still involved building 6,500 MW of nuclear plant in 2000; the government and electricity producers were planning between 10,000 and 14,000 MW at that time (Holland now has a total generating capacity of 14,000 MW and plans 39,000–56,000 MW by 2000). The nuclear research centre was meanwhile transformed into a general energy research institute, incorporating work on wind, fusion and flywheel programmes; a national programme on solar research is foreshadowed for early this year.

Breeder intention

By last autumn the Economic Affairs Minister Mr Lubbers was informing parliament almost casually of the intention of provincial and local electricity producers to take part in Superphénix, France's first commercial fast breeder. Some time before, the minister had shown some antipathy towards continued Dutch cooperation with Belgium and Germany—the three countries are building the 300 MW SNR–1 in Kalkar and are each carrying out a part of the research.

In a letter to parliament at the end of August the minister confirmed that the Netherlands was in principle continuing with the Kalkar project until SNR–1 was finished, and that Belgium and Germany had agreed to make a decision on a commercial breeder (SNR–2) then. He added that the electricity producers were involved in the SNR project, and were also in the larger European group which will develop the breeder concept further. This group, he said, would proceed with the building of the 1,240 MW Superphénix, which is based on the Phénix, before the SNR–2; as a decision to build this would be taken in the beginning of October, the electricity producers had to decide on their role.

An urgent debate was held in parliament, mainly because the Radical and Labour parties thought the Netherlands would become involved in the commercial development of a breeder before some problems were solved and vital experience was gained. As a result of one of the votes in parliament, Dutch participation is only acceptable once very strict conditions are made regarding safety aspects and international control of the project. The electricity producers agreed, and accepted the maximum financial contribution imposed on the 4,000-million guilders project, though not without some disagreement amongst themselves. By the end of the year, however, no decision to build the breeder had been taken.

Fourth time

When another nuclear subject attracted attention in October, it was for the fourth time in the year, and in this case created a problem lasting until close to Christmas. The problem concerned uranium enrichment using the gas centrifuge technique, and a definite solution is not actually expected before the end of February. The Anglo-Dutch-German group known as Urenco has pilot plants in Capenhurst in Britain and Almelo in Holland, and partly finished demonstration plants. The difficulty is that a decision is due on extensions to increase Almelo's capacity to 1,200 tonnes. Towards 1987 a further expansion for Urenco to 6,000–8,000 tonnes is foreseen, and the consortium has definite orders for 2,000 tonnes enriched uranium a year from 1983.

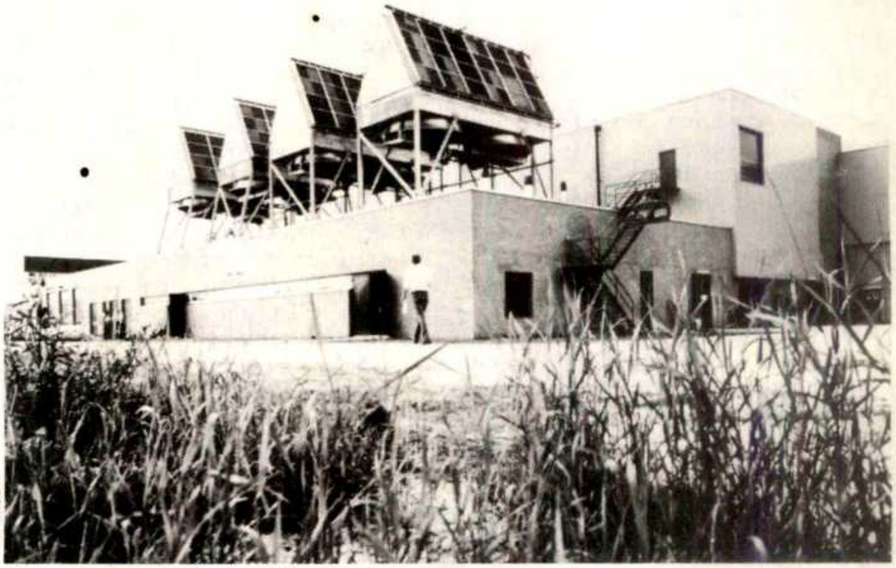
The Radicals are firmly against an expansion of the enrichment capacity for reasons connected with proliferation. There are also commercial objections, and these come not only from the PPR. Mr Lubbers has given confidential information to the parliamentary commissions for foreign, economic and nuclear affairs, but there is hesitation and doubts remain over both proliferation and the possibility of a costly overcapacity in the international enrichment market. The German–Brazilian deal is seen as particularly worrying. The Reflection Group on Energy Policy—active in 1975 before the decision on the three power plants was made—wrote a memorandum on the issue, and the PPR's own group of consultants published a report.

At the same time as all this happened the announcements from the USA and France of restrictions on nuclear exports became known, as did details of the resistance in Germany to a rapid expansion in the number of nuclear power plants. A further important point was that large commercial concerns like Shell, Philips and DSM, originally involved in the project, did not like to invest more money in it for both economic and political reasons. They believe it is impossible to work when political aspects play such a great role in decision-making.

State of crisis

A state of crisis existed for several weeks in The Hague, but the cabinet finally decided to agree provisionally to participate in Urenco's expansion, which also involves the Capenhurst plant. The parliamentary committees were informed, but it is still not clear what precisely the Dutch ministers of economic and foreign affairs will discuss with their British and German colleagues on the matter. The decision could mean domestic political problems. The Radicals are still against the idea and could conceivably leave the government. Labour and the Christian Democrats, however, are not willing to export enriched uranium to countries which have not signed the NPT. Each member of the tripartite consortium has the right of veto according to the Treaty of Almelo of 1970, and in Holland the tendency now seems to be to have this exercised not only over the export of uranium but on all nuclear exports.

At the very least, whether this government breaks up over the issue or not, the nuclear power debate will prove important in the formation of the next government. Developments during 1976 have seen to that. ☐



Urenco

Urenco's plant at Almelo, Holland

Judgment of the people

Colin Norman reports from Cambridge, Massachusetts, on the recommendations of a citizens committee established last year to look at genetic manipulation experiments

In a report likely to have important and widespread implications, a committee of citizens of Cambridge, Massachusetts, has recommended that experiments involving a new technique for manipulating genes in living organisms—recombinant DNA experiments—should be allowed to go ahead at Harvard and Massachusetts Institute of Technology. The committee said, however, that the experiments should be permitted only if they are placed under safety controls more strict than those now in force in most other institutions, and that a special board, consisting of Cambridge residents who have no affiliations with the two universities, should be established to monitor recombinant DNA research in the city.

The committee was set up last summer by the Cambridge City Council after a shrill and bitter dispute had erupted over plans to conduct recombinant DNA experiments at Harvard and MIT. At the urging of the city's colourful and irascible Mayor, Alfred E. Vellucci, the council also placed a three-month moratorium (later extended until January 7) on some types of recombinant DNA research in Cambridge while the committee conducted its investigation.

The report is far from being the last word on the matter, however. Even before the document had been formally presented to the council at a meeting held on Janaury 5, Vellucci told a few reporters that he disagreed with the recommendation that the research should be allowed to proceed in the city, and he said that he will propose a resolution at a later council meeting that some types of recombinant DNA experiments be outlawed entirely in Cambridge. Though it is generally considered unlikely that Vellucci's view will prevail in the council, the shouting is clearly far from finished.

The committee's work and its final report have won qualified praise from both sides in the dispute and, if nothing else, it has provided ample support for the view that citizens groups are well qualified to consider and pass judgment on complex technical issues. The committee, which was chaired by Dan Hayes, a former Cambridge Mayor, was thrust into the middle of a highly charged political and scientific conflict, and it has acquitted itself admirably.

Events in Cambridge are important in the context of national and international efforts to control recombinant DNA research. Those efforts began in 1974 when a group of scientists went public with their concerns that genetically modified microorganisms produced in recombinant DNA experiments might pose a hazard to public health if they should escape from the laboratory and survive in the environment. Last June, the National Institutes of Health (NIH) published a set of guidelines designed to guard against such a possibility. They define four levels of physical containment to be used for recombinant DNA experiments, designated P1 to P4, and the guidelines assign experiments to them on the basis of potential risk.

In addition, the guidelines specify that some experiments should only be carried out on crippled strains of microorganisms which have a limited capacity to survive outside the laboratory. The restrictions formally apply only to research supported by NIH, however, and they have encountered considerable criticism from opponents of the research.

While the guidelines were being drafted, plans were drawn up to construct a safety laboratory at Harvard at which some recombinant DNA research would be undertaken. Under the definition in the NIH guidelines, it would be a P3-level facility. A similar laboratory had already been constructed at MIT for cancer research, and it was also expected to house some recombinant DNA experiments. The proposed Harvard lab became a source of dispute between opponents and proponents of the research, and the conflict spilled over into the city council after an article was published in a local newspaper.

Town-gown relationships have never been very friendly in Cambridge, and Vellucci quickly latched on to the issue. After two extraordinary council meetings in late June and early July at which the warring scientific factions presented their views, the Council imposed a moratorium on P3- and P4-level experiments in Cambridge and asked the citizens' committee to recommend the circumstances, if any, under which such research should be permitted.

The committee's investigation is thus the first detailed review of the NIH guidelines to be carried out by a group composed entirely of nonscientists. It should be emphasised, however, that it was asked to consider only P3 and P4 experiments, and thus it was not asked to consider the rationale used by NIH in assigning experiments to different safety levels. It was also asked to consider only the potential health hazards of the research and it therefore steered clear of such emotive issues as whether the research might lead to undesirable applications.

After conducting lengthy public hearings and poring through reams of written material, the committee reached the unanimous conclusion that P3-level experiments can be permitted in Cambridge under certain conditions. Since no P4 facility is planned in the city, the committee said nothing about P4-level experiments, though it implied that they should not be carried out there. The chief condition set by the committee is that all recombinant DNA experiments should be performed with strict adherence to the NIH guidelines, but it also recommended the following additional safeguards:

- All laboratory personnel should receive adequate training in safety procedures, and institutions planning to carry out such experiments should produce a manual of procedures.
- Under the NIH guidelines, biohazards committees must be established in institutions where recombinant DNA experiments are conducted, and the Cambridge committee recommends that they should contain technicians and at least one representative from outside the institution.
- All P3 level experiments conducted in Cambridge should use crippled strains of microorganisms.
- Institutions must conduct tests to ensure that experimental strains of organisms are pure and that they are not resistant to common antibiotics.
- Institutions in which recombinant DNA experiments are performed must "in good faith make every attempt, subect to the limitation of the available technology" to monitor for the escape of host organisms, and "this should include whatever means is available to monitor the intestinal flora of the laboratory worker".
- Finally, the committee's most interesting recommendation is that a Cambridge Biohazards Committee (CBC) be established "for the purpose of overseeing all recombinant DNA research that is conducted in the City of Cambridge". The Board would be composed of people appointed by the city manager and its members would have no affiliations with the universities. Its functions would include reviewing pro-

posals for recombinant DNA research to ensure that they would comply with the NIH guidelines, maintaining links with the biohazards committees at Harvard and MIT, and "developing a procedure for members of institutions where the research is carried out to report to the CBC violations either in technique or established policy".

In addition, the committee urged Congress to pass legislation extending the NIH guidelines to cover all recombinant DNA research in the United States and to set up a national registry of laboratory workers for long term epidemiological studies.

The report has been welcomed by supporters of the research. David Baltimore, a tumour virologist at MIT's Cancer Research Center, said in an interview last week that the report "is basically a vindication of the whole process which began with the NAS committee", which raised the first concerns about the potential hazards associated with the research.

Opponents of the research are disappointed that the committee didn't come down in favour of banning the research in Cambridge, but they also agree with much of the report. In particular, Jonathan King, an MIT biologist who has been among the more outspoken opponents, noted in an interview that creation of the CBC would be a good step toward more citizen control over research and it would lead to increased accountability of scientists to the public. He also welcomed the suggestion that the health of laboratory workers be monitored, but suggested that unless pressed the universities would drag their feet in implementing the recommendation.

The ball is now back in the City Council's court. At the meeting on January 5 when the report was publicly unveiled, the council passed a resolution extending the moratorium on P3-level experiments in Cambridge for a further 30 days to allow time to consider the recommendations and to hear responses from the universities. Vellucci has promised to introduce a resolution banning P3- and P4-level experiments entirely and making scientists who conduct such research liable for a fine of $1000 per day. Another resolution will be proposed to implement the committee's report.

- One Cambridge Councillor, David Clem, said last week that he expects the report to be well received, and that the matter will probably be cleared up before the extended moratorium is scheduled to end. He noted, however, that he has some reservations about the recommendations and will wait to see what plans the universities have for implementing them before he decides how to vote.

Finally, it should be noted that other local governments, particularly the New York Attorney General's office, are taking a close look at the control of recombinant DNA research. The fact that a committee of non-scientists has recommended in favour of going ahead with the research, albeit under strict controls, will not pass unnoticed. □

PAKISTAN

New policy on the anvil

Azim Kidwai reports from Karachi on changes expected in Pakistan's science policy framework

THE economic, social and cultural changes that have occurred under the Bhutto government—they include nationalisation of almost all domestic banks and insurance companies, of the heavy industrial and parts of the agricultural sector, but not consumer goods industries like textiles, tobacco, chemicals and pharmaceuticals—have naturally had an impact on science policy. A new national policy now on the anvil is the result of lengthy deliberations amongst the elite of the scientific community and representatives of various scientific organisations and government agencies. Final proposals are expected once they have been discussed at Cabinet level.

The existing arrangements for scientific and technological research in Pakistan appear to suffer from three weaknesses: coordination of effort at national level is lacking; the universities have a very weak base as far as scientific research goes; and no effective mechanism exists for the utilisation of the results of research. At the apex of the structure of science in Pakistan lies the Ministry of Science & Technology of the central government assisted by the National Science Council and the Pakistan Science Foundation.

The National Science Council was created as a coordinating body for the different Research Councils and to advise the government on promotion of science in general, but in practice rarely discharged those functions effectively, possibly because it had no financial or budgetary strings to pull. It thus remained but a shadow of what it was originally conceived to be. The Pakistan Science Foundation was created subsequently as a sponsoring body to help promote financial support for university research work and promising individual research workers, for pilot plant studies, for the establishment of science museums and for scientific societies. This it has been doing within the limits imposed by the funds at its disposal.

This triangle at the top lacked coordination, and in practice was not up to implementing a vigorous science policy fully integrated into the national development effort. Suitably informed decisions could not be made at the top political level, and administrative coordination was inadequate, particularly in respect of planning. The proposals for the new science policy try to take account of these weaknesses. A National Council for Science and Technology is proposed as the supreme body to provide guidance on all matters pertaining to formulation and implementation of government policy on science and technology. It should also be responsible for planning, coordination and cooperative implementation of scientific and technological programmes. The proposed National Council may be headed by the Prime Minister, and the central ministry for science is to act as its secretariat.

The Research Councils—the Pakistan Council of Scientific and Industrial Research, Pakistan Medical Research Council, Irrigation, Drainage and Flood Control Research Council, Council for Works and Housing Research, Agricultural Research Council and the recently approved Livestock Research Council—are likely to be given autonomous character and resources to organise mission-oriented research in their specialised fields.

Some idea of the scope of R&D effort through these institutions can be gained from the budget figures for the current year, which reflect to some extent their relative weaknesses and strength. These are shown in the accompanying table. □

Pakistan's science research budget 1976–77

Council	Rupees
Scientific & Technological Research Division of the Ministry	1,998,000
National Science Council	443,000
Pakistan Science Foundation	5,500,000
Pakistan Council of Scientific and Industrial Research	29,320,000
Pakistan Medical Research Council	1,506,000
Irrigation, Drainage and Flood Control Council	740,000
Council for Works and Housing Research	820,000

£1 = 16.5 Pakistani rupees

The nuclear debate

SIR,—I believe *Nature* is right to enlarge the nuclear debate to the general, international scene but I wonder if both sides can be represented fairly. Döderlein's essay (November 18, page 202), which presents one side of the issue, needs to be balanced by these points:

- The battle is one-sided. Pro-nuclear propagandists are paid; the opposition is not. Most nuclear "experts" are employed by the nuclear industry, which has money to spend. For example, anti-nuclear forces were outspent four to eight or more times in the six states where initiatives were balloted in November (*Science*, November 19). Another disquieting factor is that nuclear industry representatives seem to want to exclude biologists, environmentalists and other concerned members of the general public from the controversy. This approach does not generate confidence.
- Your opponent is always "irrational", as I find Döderlein. I also object to his suggested dichotomy: "reasonable, rational and valid" (or "reasoned, factual and rational") versus "irrational, emotional and ethical". One wonders what Döderlein's definition of rational might be.
- In my opinion humanity should be glad certain persons " . . . play out some of their inner and emotional needs by taking an active part in the nuclear controversy . . . ". These "needs" may be a safety valve for society. Humans resist becoming robots, they have emotions and let us hope they will continue to learn to express them for our collective betterment. Also, "emotional" and "irrational should not be confused; an emotional approach can be disciplined by rationality and even by the scientific method. Emotionlessness is not unjustly linked with death.
- The fact that already " . . . industry . . . gives uncontrolled releases . . . of substances which remain toxic for infinite times . . . ", if true, would hardly be an argument for accepting nuclear wastes. Furthermore, all toxic materials do not have the same toxicity and we are not obliged to make an unweighted choice among them.
- Practically all the plutonium present on earth, contrary to Döderlein's implication, has been produced by man-made nuclear reactors. No natural source of plutonium is known although trace quantities have been reported in uranium deposits. Any plutonium that might have existed on the primitive earth (of 4.6×10^9 years ago) would have long since disappeared because of plutonium's relatively short half life.
- "Medical" reactors may be much smaller than the bomb-capacity commercial reactors planned, hence medical reactors and small research reactors are less directly linked to the spread of nuclear weapons. I believe many people, some nuclear experts included, would like to see *more* nuclear research. We are alarmed by the planned installation of hundreds of big reactors all over the earth without enough research having been done, especially on medical and genetic risks to nuclear workers and the general public. Some of these reactors will contain *tonnes* of plutonium (see Frank Barnaby, The SIPRI Yearbook, 1976). Inhaling a few microgrammes can kill you.
- Finally, Döderlein asks " . . . can anything short of actual war stop a determined sovereign nation from getting primitive but usable versions of any kind of contemporary weapons technology—nuclear, bacterial, chemical or any other?" I say war could lead to have-not nations getting nuclear and other modern killing techniques, especially if such countries align themselves with the "right" side in the conflict. In this context, both sides would probably be the right side. So, let us try something short of war.

It seems to me that instead of trying to restrict the discussion to experts we should indeed extend it to everyone. This would encourage a human synthesis, an overall approach on world problems that no one discipline or industry can provide. Our capacities for arriving at common solutions will obviously have to be developed. This could be helped by de-specialising scientific and philosophical methodologies, which could be combined and applied to questions such as disarmament, the energy and food crisis and nuclearisation of the earth. A convergence and interaction between science and philosophy is necessary for just solutions and a stable future world, if it is to be democratic.

CERN'S project management

SIR,—In your article of November 25 marking the completion of the CERN 400 GeV SPS you paid rather less attention than might have been expected to the fact that the project has not only comfortably exceeded its original specification in several important respects, but has also been completed on time and within its budget. The excellence of CERN's project management is self-evident, but the matter cannot be left there.

It has been said that CERN is an exacting customer both technically and financially, because it takes great pains to define its requirements precisely and because it usually has a clear idea in advance of how much it will need to pay. On the other hand, it can be a cooperative if tough customer, providing technological expertise, advice and highly-qualified personnel to contractors who experience problems during production. The advantages to both sides in this close relationship are obvious, even though the efficient use of outside technological help may sometimes have to be imposed upon an unwilling firm.

Building the SPS has involved the development of working relations with hundreds of firms throughout Europe. Although CERN's contributions to advanced technology and the economic utility of its contracts have been fully documented[1,2], its influence as a good customer has perhaps been underestimated, if only because the immediate financial gains are almost impossible to quantify. Now that the customer-contractor principle is established as a fundamental concept behind much British research funding, it is essential to re-emphasise the point that the ultimate success of a complex scientific project depends as much upon the competence and scientific expertise of the customer as upon the performance of the contractor.

news and views

Nations and numbers 1976

from Robert M. May

LAST year I gave a summary (*Nature*, **261**, 12; 1976) of the 1975 estimates of population magnitudes, growth rates, age structures, and patterns of urbanisation which were compiled for individual countries and for regional groupings by the Environmental Fund (1302 Eighteenth St, Washington, DC). Their 1976 wall-chart shows much the same figures, with the total world population swollen by about 94 million to an estimated 4,241 million, and still growing at around 2.2% per annum.

The many uncertainties in population estimates are perhaps best illustrated by the figures for the USA. The Environmental Fund gives the mid-1976 population to be 222.2 million, as opposed to the US Bureau of the Census figure of 215.7 million. The discrepancy arises because the official figure does not include the undercount of about 5.3 million which has been announced by the Bureau for its most recent census in 1970, nor does it include an estimated 1.2 million illegal immigrants (constituted of 800,000 who entered illegally and evaded deportation, and 400,000 from among the 11 million foreign visitors who entered legally during the past year).

Such uncertainties are writ large for China, which has issued no official figures since 1956. Estimates of the current Chinese birth rate range from 37 to 17 per 1,000. The Environmental Fund chart uses Aird's 'intermediate model' (Foreign Demographic Analysis Division, US Department of Commerce, 1975) for the population of China. This is substantially higher than the US Bureau of the Census estimate, whose world population figure is consequently 4,069 million. The UN estimate for China is yet lower; highest is the CIA estimate.

Overall, the UN estimates the world birth rate to be 33 per 1,000, one less than it was 20 years ago. The Environmental Fund chart shows 35 per 1,000. As available data are not accurate to better than 2 per 1,000, the exact number is anyone's guess.

The chart also summarises the number of acres of arable land per person (from the 1974 United Nations Food and Agriculture Organisation, *Production Yearbook*, **28**). Although there are considerable difficulties in definitions here, the trends are interesting: an average of 1.2 arable acres per person in Africa; 0.5 in Asia; 2.3 in North America; 0.8 in Latin America; 0.7 in Europe (0.3 in the United Kingdom); 2.2 in the USSR; 5.3 in Oceania. Among countries with more than 10 million inhabitants, low is 0.1 for Holland, Japan and South Korea, and high is 8.1 for Australia.

Of the 158 countries listed in the chart, 35 were net exporters of cereal grain in 1948–1952; 18 remained in 1974 (UNFAO *Trade Yearbook*, **14**, 1960 and **28**, 1974). By regional grouping, the figures for net export of cereal grain, in millions of metric tons, 'then' (1948-1952) and 'now' (1974) are: Africa, −0.4 and −6.9; Asia, −5.8 and −47.1; North America, +22.5 and +76.4; Latin America, +1.2 and −0.4; Europe, −20.8 and −28.5 (United Kingdom, −6.9 and −7.3); USSR, +2.1 and +0.7; Oceania, +3.2 and +6.9.

These and other similar figures underlie the UN projections for annual growth in food supplies and in population until 1985 (see Murdoch and Oaten, *BioScience*, **25**, 561; 1975). For Africa, the projection is for 2.5% per annum growth in food supplies and 2.9% in population, for Asia (excluding China), 2.4% in food and 2.6% in people; for Latin America, 2.9% and 3.1%. Summing over all 'rich countries', the projections are for 2.8% per annum growth in food supplies and 0.9% in population; for 'poor countries', 2.6% and 2.7%. These trends are disturbing. They are made more so by the facts that the projections ignore rising energy costs, that a large fraction of the world population is malnourished at present and that the past UN projections have consistently erred towards optimism. □

Multiple controls in bacteria

from John Scaife

THE early choice of bacterial fermentation systems for gene control studies was a fortunate one. They prove to be excellent models of multiple gene control, readily analysed both *in vitro* and *in vivo*. The control of the lactose (*lac*) operon for example has two known components: a repressor protein and a protein termed CRP. The repressor, which directly governs the bacterium's response to β-galactosides, blocks the binding of RNA polymerase to its site in the promoter where transcription is initiated. CRP actively facilitates this binding step (see Gilbert in *RNA Polymerase*, edit. by Losick, R., and Chamberlin, M., Cold Spring Harbor Laboratory, 1976) using 3′, 5′-cyclic AMP as a cofactor. It thereby mediates in the *lac* operon the repressive effect of glucose (catabolite repression) to which many degradative operons are subject. Glucose modulates the amount of cyclic AMP in the cell.

Within the *lac* promoter the CRP-binding sequence (Beckwith, Grodzicker, and Arditti, *J. molec. Biol.*, **69**, 155; 1972) has now been identified among promoter fragments *in vitro* (Majors, *Nature*, **256**, 672; 1975). It lies upstream from the polymerase binding site. Interestingly the normal polymerase site in *lac* deviates significantly from other sequenced polymerase sites (Pribnow, *Proc. natn. Acad. Sci. U.S.A.*, **72,** 784; 1975). There is, however, a mutant, *UV5*, whose sequence is more in line with the others (see Gilbert, *op. cit.*). This strain does not require CRP for efficient *lac* function. The lesson is clear; CRP compensates for otherwise poor interactions between RNA polymerase and the normal *lac* promoter. How it compensates remains an unanswered question of great interest.

This well-founded and simple view of catabolite repression may nevertheless be incomplete. There is evidence that it might be mediated by more than one mechanism (Ullman, *Biochem. biophys. Res. Commun.*, **57,** 348; 1974). The behaviour of the galactose (*gal*) operon of *E. coli* has appeared particularly paradoxical. *In vitro* studies (Nissley, *et al.*, *J. biol. Chem.* **246,** 4671; 1971) clearly implicate CRP in *gal* function, yet mutants lacking CRP or cyclic AMP give good *gal* expression *in vivo* (Rothman-Denes, Hesse, and Epstein, *J. Bact.*, **114,** 1040; 1973).

New evidence for a second system mediating catabolite repression has just appeared. (Ullmann, Tillier, and Monod, *Proc. natn. Acad. Sci U.S.A.*, **73,** 3476; 1976) have partially purified from *E. coli* a new factor (CMF) which represses catabolite-sensitive operons in growing bacteria. The factor could resolve some of the present anomalies. It is unlikely to act by degrading CRP or cyclic AMP. It could interfere with inducer uptake or affect transcription directly.

There is, however, a different explanation for the *gal* paradox. It is suggested by features of the newly elucidated *gal* promoter sequence (Musso, Di Lauro, Rosenberg, and de Crombrugghe, *Proc. Natn. Acad. Sci. U.S.A.*, in the press). The *gal* operon has in its promoter binding sites for CRP and RNA polymerase like those of the *lac* operon. In *gal*, however, there are two start points for transcription. One of them uses CRP and cyclic AMP; the other does not, and in fact is inactive in their presence. Thus Rothman-Denes and coworkers were probably observing the CRP-independent mode of *gal* transcriptions.

Why should there be two transcription modes in this operon? The bacterium uses galactose in two quite different ways—as a carbon source and a cell-wall component—providing two metabolic contexts for *gal* enzyme synthesis. How they are distinguished can now be understood. Galactose as a carbon source induces the operon by inactivating the repressor. Musso *et al.* show that this requires transcription in the CRP mode, since the *gal* repressor hinders the binding of CRP, not polymerase. Without exogenous galactose, however, the operon must remain partially active to permit growth. This requirement can be satisfied by transcription, in the CRP-independent mode, despite the active repressor in the cell. The way is now open to tackle the challenging problem of how CRP-independent *gal* transcription is related to the growth process. Could it involve CMF? □

Fusion in Berchtesgaden

from J. G. Cordey

The sixth International Conference on Plasma Physics and Controlled Nuclear Fusion Research was held at Berchtesgaden in Bavaria on October 4-15, 1976. A more detailed account, which includes progress in fields of reactor design and inertial confinement (not discussed here) will be published soon in *Nuclear Fusion.*

DURING the past few years significant progress towards achieving thermonuclear fusion conditions has been made using the tokamak approach. This has been mainly due to the considerable effort that has gone into this field, which to some extent has been at the expense of the other containment geometries. The plasma physics behaviour in a tokamak is not yet fully understood, but experimental scalings at present suggest that fusion conditions can be obtained in a modest sized experiment. As far as the other containment approaches are concerned the route to a reactor is less clear.

Since the last meeting in this series, held in Tokyo in 1974, several new experiments have been commissioned. In particular the first results from two new large toroidal experiments T-10 and PLT were presented. Both these experiments are of the tokamak type, PLT (Princeton Large Tokamak) is at the Princeton Institute of Plasma Physics in the USA and T-10 at the Kurchatov Institute in the USSR. The machines have similar dimensions, the major radius of the torus in T-10 is 150 cm (PLT, 130 cm), the minor radius 39 cm (PLT, 40 cm). The toroidal field was operated at 3.5 T in both devices. The discharge current in these devices was 0.4 MA in T-10 and 0.59 MA in PLT. This current, which is in the toroidal direction, is essential for the formation of a plasma equilibrium and also heats the plasma by ohmic dissipation.

The parameters of the plasma contained in the two devices were broadly similar; the electron temperature in the centre of T-10 was 1.2 keV (1.9 keV in PLT), the ion temperature 0.6–0.8 keV (0.9 keV in PLT), the plasma density (n) 8×10^{13} cm^{-3} (3.5×10^{13} in PLT). The major difference between the two experiments was in plasma purity. In T-10 the plasma was rather pure having an effective charge between 1 and 2 whereas in PLT the effective charge was between 5 and 7. The energy containment time τ in T-10 was 0.06 s (0.04 s in PLT), giving an $n\tau$ (the Lawson product) of 5×10^{12} cm^{-3} s. Although the value of $n\tau$ and the ion temperature are both short of what is required in a reactor ($n\tau \sim 10^{14}$ cm^{-3} s and an ion temperature of 10 keV), they are a substantial improvement on the results obtained in smaller machines operated with the same magnetic field.

There was much discussion about the scaling of the energy confinement time τ between these larger experiments and the smaller experiments. The general consensus was that the energy containment time was scaling as the minor radius to the power α ($\tau \propto a^{\alpha}$) with α lying somewhere between 1.5 and 2. This result is quite encouraging and provided this type of scaling extends into the higher temperature region needed in a reactor, then it should be possible to achieve reactor conditions in a tokamak of modest size.

Moving on to the smaller tokamak experiments, the strong scaling of $n\tau$ with magnetic field strength has been demonstrated in the Alcator tokamak at MIT. Alcator is a small tokamak, major radius 54 cm, minor radius 9 cm, but has been operated with very high magnetic fields up to 8 T. At the highest magnetic fields, densities of 7×10^{14} cm^{-3} and containment times of 0.02 s have been achieved giving an $n\tau$ of 10^{13} cm^{-3} s. Thus it seems that high magnetic fields have a significant effect on the plasma containment and allow operation at higher density.

The neutral injection heating of tokamaks has continued to be successful. Ion temperatures up to 2 keV have been obtained in TFR and Ormak, and the increase in ion temperature is proportional to the injected power. The ion energy confinement time seems to be independent of temperature and does not follow the neoclassical scaling law at these higher temperatures.

The initial experiments on the DITE tokamak at Culham using the 'Bundle Divertor' are also quite encouraging. The purpose of a divertor is to remove impurities from the edge of the plasma. (Impurities poison the plasma and lower the temperature of the edge region.) The bundle divertor consists of two coils whose magnetic field distorts the main toroidal field such that the field lines at the edge of the plasma are diverted into an external pumping chamber before returning to the torus. The divertor on DITE is only operating at low toroidal field at the moment, but has successfully reduced the influx of gas and impurities to the plasma; as yet there has been no increase in electron temperature however.

A complete theoretical explanation of tokamak containment is not yet available, but present indications are that in the middle of the device the containment is determined by magnethydrodynamic instabilities and in the outer region is lost mainly by radiation. In the intermediate region drift wave turbulence is thought to be responsible for the energy loss. Measurements of the amplitude of the drift wave spectrum in the TFR tokamak at Fontenay however, indicated that it was not sufficient to account for the thermal conduction in this region.

Turning to other containment devices there was a revival of interest in stellerators at the conference. Results were presented from three new stellerator experiments—W7A at Garching, L2 in the Lebedev and Cleo at Culham. All these machines are smaller than the present generation of tokamaks, with minor radius of around 10 cm. Their energy containment time was typically between 1 and 8 ms with electron temperatures up to 800 eV. These results are clearly an advance over those obtained in the model C stellerator experiment at Princeton some years ago and are comparable with tokamaks of similar size and field strength. In fact these machines can be run in either a pure tokamak mode by not energising the stellerator helical windings or a stellerator–tokamak hybrid mode. Comparisons were made between the two types of operation and it was found that with the stellerator field on, the containment time was increased. Thus it seems that the extra complication of the stellerator helical winding can give worthwhile improvement in containment. I think, however, that the difficulty of designing suitable helical windings for large-scale devices with stronger magnetic fields may restrict progress in this field.

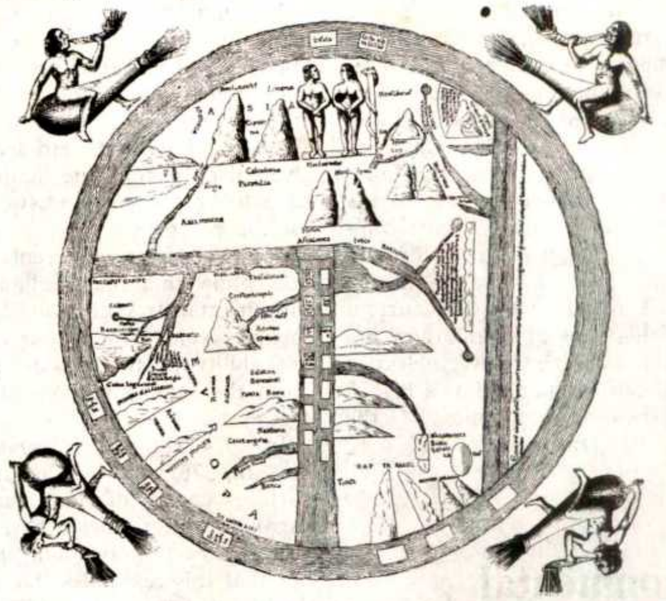
Both the tokamak and the stellarator are toroidal containment devices and in these the magnetic field lines stay within the plasma volume. There is another class of linear containment device however, and in these the force lines leave the plasma volume at the ends. The most important member of this class is the mirror machine, and in this device the plasma is trapped in the magnetic well formed between two coils, the particles 'mirroring' between the high-field regions close to the coils.

There has been a considerable increase in understanding the physics of mirror machine containment in the past 2 years, mainly due to experimental work on the 2XIIB machine at Livermore. Using very powerful neutral injectors delivering in total 5 MW of power at an energy of 20 keV, plasma densities of 10^{14} particles cm^{-3} at a mean ion energy of 13 keV have been built up from a target gas. To suppress the amplitude of ion cyclotron microinstabilities a warm plasma stream is injected along the field lines; unfortunately this stream also cools the electrons. In fact the electron temperature was less than 100 eV and this low electron temperature resulted in the rapid cooling of the injected ions; the energy containment time was typically of the order of 0.001 s giving an $n\tau$ of 4×10^{10} cm^{-3} s. The average value of β, that is the ratio of plasma pressure to the magnetic pressure, was very high —of the order of 0.7. This may be compared with tokamak β values which are typically of the order of 0.01, so the mirror machine is very economic in the use of magnetic field. It is this, along with its simplicity, that makes the mirror machine attractive from the reactor designer's point of view.

The basic problem with the mirror machine, however, is the rapid loss of plasma through the ends of the device. As well as losses caused by classical Coulomb collisions, there are additional losses due to microinstabilities which are driven by the anisotropy of the velocity distribution of the mirror-contained plasma. There are good theoretical arguments for expecting these microinstabilities to be less important in reactor scale devices with larger radius. But even if the only losses were classical, a self-sustaining mirror reactor would not be possible, and the device would have to be operated as an energy amplifier. Unfortunately the energy amplification factor Q is rather low, of order 2, and several schemes have been advanced for raising Q to around the 10 or 20 required for an economic mirror reactor. At this conference a novel triple mirror scheme was proposed by Dimov *et al.* (IAEA Conference Berchtesgaden paper C4). The idea is to place a small mirror machine at each end of a large mirror machine. The temperature and density in the outer mirror machines were maintained by high energy (~ 1 MeV) neutral injection at a higher level than the temperature and density of the main inner miror machine. The resulting ambipolar potential of the outer mirror machines reflected the ions in the inner mirror thereby improving their containment. By suitably adjusting the ratio of the lengths of the central mirror machine to outer mirror machines, it was thought that Q values in the region of 5–10 could be obtained.

Fortunately, no basically new types of instability have been found during recent theoretical work and most of the theoretical papers were concerned

A hundred years ago



Tenth century map of the world exhibited at the International Geographical Congress in Paris. From *Nature* **15**, January 11, 234; 1877.

with analysing the effects of existing modes in more realistic geometry. There was also an interesting and welcome trend in that theoreticians were attempting to compare their predictions with experimental results.

The Oak Ridge theoretical group gave an analysis of the flux-conserved tokamak equilibrium. These equilibria are attained by increasing the plasma pressure in a time which is short compared with the magnetic field diffusion time. In this manner β values of the order of 0.3 are achieved. The current profile of this type of equilibrium has not yet been examined; nevertheless, if a tokamak can be operated at a high β then the reactor economics of the device will be greatly improved. ☐

Environmental stress cracking

from P. D. Calvert

WHEN the bottom of a polyethylene bucket splits after six months use the cause is probably environmental stress cracking. The action of detergent solutions and residual stresses from the moulding process cause the slow growth of a crack which usually follows the boundaries of the polyethylene spherulites. Fifteen years ago this was a matter of great industrial concern as coverings on underground cables were prone to crack at bends. It was found, however, that the problem could be largely eliminated by suitable control of the grade of polymer and moulding conditions and the level of industrial interest decreased. But some progress has since been made on the more academic question of why this cracking occurs.

The phenomenon of environmental stress cracking has been extensively reviewed (see Howard, *Soc. Plastics Eng. J.*, 397; 1959; *Engineering Design for Plastics* (ed. Baer, E., Krieger, Basel; 1964)). Cracking is sensitive to the molecular weight distribution of the sample and in particular cracking resistance is improved by removal of the lowest molecular weight species (Herman and Biesenberger, *Polymer Engineering Sci.*, **6**, 341; 1966), which probably segregate to the spherulite boundaries and weaken them. Tests for stress cracking measure the time to fracture of a sample either bent and immersed in a liquid, or held under constant load in the liquid.

High density polyethylene is more resistant than low density to stress cracking under a constant load, but the situation is reversed when bent samples are tested. Fire polishing improves resistance to stress cracking, presumably by removing small surface flaws.

The liquids which cause stress cracking in polyethylene tend to be of low viscosity and to be surface active. Non-ionic detergents are quite effective, as are silicone oils, mineral oils and alcohols, but not ethylene glycol, glycerol or water. The liquid does not have to be a solvent or swelling agent for the polymer.

From a series of recent studies we now know that the mechanism of environmental stress cracking at low loads, involves void growth and depends on the ability of the liquid to penetrate from the sample surface to the crack tip.

In 1974 Hannon (*J. appl. Polymer Sci.*, **18**, 3761) showed that the fracture surfaces consist of small smooth areas surrounded by zones where the polymer has been drawn out. He pointed out that this resembles the situation in ductile fracture surfaces of metals where fracture starts by the growth of voids around particulate inclusions and ends when the voids grow large enough to join up. In polyethylene the voids must start at locally weak regions. Addition of detergent to the testing environment results in larger voids with less deformed material. Berg (*J. Res. NBS*, **76C**, 33; 1972) discussed theoretically the process of cavity growth in metals and suggested that this could be applied to stress cracking in polymers.

At high loads the crack velocity can become sufficiently large that the progress of the crack tip is limited by the ability of the liquid to flow in. On this basis Williams and Marshall (*Proc. R. Soc.*, **A342**, 55; 1975) made a fracture mechanics analysis of stress cracking and predicted a change in the stress dependence of crack speed, which they observed to occur at about 3×10^{-7} m s^{-1} in a detergent. Shanahan and Schultz (*J. Polymer Sci.*, (*Phys*), **14**, 1567; 1976) have now established this change by measuring fracture times of polyethylene samples in a series of silicone oils of different viscosity. At low loads the time to failure is independent of viscosity but for each viscosity a critical rate is reached above which the failure time changes only slowly with load. This critical time to failure is roughly proportional to the fluid viscosity. The most obvious interpretation of this is that the total time to fracture is the time it takes the crack to grow, but Shanahan and Schultz make the rather more elaborate assumption that when, by creep, a critical strain of 15% is reached, fracture occurs rapidly at a rate proportional to the creep rate. This, however, is a point which ought to be easily cleared up.

Although this gives us a good idea of how the fracture occurs it does not help to explain why polyethylene is the only polymer in which it happens and why some liquids are more effective than others. Spendal (*J. appl. Polymer Sci.*, **16**, 2375; 1972) has shown that the addition of 10% rubber can dramatically improve stress crack resistance, presumably by toughening the boundary regions. With rather more subtlety Schonhorn *et al.* (*J. Polymer Sci.* (*Phys*), **11**, 1013; 1973) have shown that the addition of silanes to polyethylene can improve stress crack resistance and base their arguments on the ways in which the interfacial energies of polymer–polymer and polymer–liquid are modified.

There are many other cases where polymers do form voids under stress both with and without environmental agents; the phenomenon is generally called crazing. Why this should be so common amongst polymers and why only polyethylene is vulnerable to the peculiar form of voiding discussed above is not known although Haward (*The Physics of Glassy Polymers* Applied Science, 1975) has discussed the question in some detail. But the solution to this problem is unlikely to help the humble plastic bucket. ☐

Serpentinite in the oceanic crust?

from Peter J. Smith

IT is now more than 14 years since Hess (in *Petrologic Studies*, Geological Society of America, 1962) suggested that serpentinised peridotite is the major constituent of seismic layer 3 of the oceanic crust. In the debate that has gone on throughout most of the intervening period, arguments have been adduced both for and against the proposal, although the balance of belief now seems to be against it. As the serpentinisation of peridotite can only occur below 500 °C, Hess envisaged the hydration of upper mantle peridotite taking place upon the latter's moving upwards through the 500 °C isotherm beneath an oceanic ridge; but as Fowler (*Geophys. J.*, **47**, 459; 1976) has recently pointed out, the depth and proximity of layer 3 to the ridge axis combined wth a reasonable thermal model of the crust militate against widespread serpentinisation. Moreover, as Cann (*Geophys. J.*, **15**, 321; 1968) has noted, the very small scatter of layer 3 seismic velocities would imply an unacceptably high uniformity of serpentinisation throughout the layer.

Cann's alternative suggestion is that the lower oceanic crust consists largely of gabbros and metagabbros. But even so, it does not follow that serpentinite plays no part at all in crustal formation. On the contrary, it is evident that serpentinite bodies are closely associated with the major tectonically active fracture zones offsetting ridge axes. For example, the steep south wall of the Vema fracture zone which offsets the mid-Atlantic ridge by 320 km at 11°N is the edge of a serpentinite intrusion running parallel to the fracture and thus orthogonal to the ridge. And similar bodies, probably emplaced diapirically from the upper mantle, are also found in conjunction with offsets of the Indian ridge.

But serpentinisation in association with major fractures is a special case in that it is localised. Does serpentinised peridotite play any significant part in the formation of 'normal' oceanic crust along ridges? Bonatti (*Earth planet. Sci. Lett.*, **32**, 107; 1976) now suggests that it does—not in the form of a continuous layer *à la* Hess but as vertical solid intrusions, or 'protrusions', and associated subhorizontal sills. The proposal here is that serpentinite bodies resulting from the hydration of upper mantle peridotite "move gradually upwards into the crust by solid diapirism during the initial stages of crustal spreading, and become emplaced along narrow bands parallel to ridge axes". By 'narrow' Bonatti means of the order of a few hundred metres; and the bands lie between the supposedly faulted blocks of basalt (layer 2) and gabbros/metagabbros (layer 3) which make up the bulk of the crust.

There is certainly evidence for the presence of serpentinite in the oceanic crust away from major fracture zones, at least in the Atlantic. For example, Aumento and his colleagues (see Aumento and Loubat, *Can. J. Earth Sci.*, **8**, 631; 1971) have reported that serpentinite outcrops are common near the mid-Atlantic ridge at 45°N. Numerous serpentinite samples have also been dredged from the north wall of the Vema fracture at 11°N. The latter, being found close to a major fracture, could be the result of fracture zone volcanism and thus irrelevant to the point at issue, although Bonatti offers convincing evidence for regarding the north wall of the Vema fracture (in contrast to the south wall) as a section of 'normal' crust. In any event, serpentinite samples from both sites share characteristics; they are restricted to no single crustal layer, they become shallower with distance from the ridge axis and they do not occur within a few tens of kilometres of the axis.

All of which would seem to support the idea of serpentinite diapirism. As Bonatti envisages it, the serpentinisation is due to sea water which both acts as hydrating agent and keeps the lower crust below the 500 °C isotherm. The process begins at the fractured margins of the ridge axial zone and extends laterally away from the ridge for perhaps 100–200 km. Vertically, it occurs to depths of several kilometres, probably even down to the crust–mantle boundary. The upward mobility of serpentinised mantle is made possible by the existence of deep dip-slip faults parallel to the ridge axis (the result of block faulting) and the low strength and density of serpentinite compared with other crustal rocks. Finally, assuming a ridge spreading velocity of 1.2 cm yr^{-1}, Bonatti estimates the rate of ascent of the serpentinite diapirs to be about 1 mm yr^{-1}.

The serpentinite diapirs proposed are too narrow to be detectable seismically, but there may be other direct and indirect ways of deducing their presence. For example, serpentinites often have high magnetisations, probably due to the formation of secondary magnetite, and thus give rise to strong magnetic anomalies. If the Bonatti thesis is correct his oceanic diapirs should give rise to narrow anomalies superimposed upon the wider Vine-Matthews anomalies; and since the diapirs supposedly enter crust already thousands to millions of years old, their magnetic polarity should not necessarily agree with that of the surrounding crust. In fact, short-wavelengths linear anomalies of the suggested type have already been reported by several workers although unfortunately there are other equally possible explanations for them.

Perhaps the best test, however, is direct sampling. Serpentinite bodies in the oceanic crust have already been encountered on several occasions during the work of the Deep-Sea Drilling Project. Sub-parallel strips of intrusive serpentinised ultramafics of the order of 100 m wide have also been found in gabbros and basalts in a part of Macquarie Island believed to be a section of uplifted Cenozoic oceanic crust. There must surely be other examples.

Energetic nuclear collisions

from P. E. Hodgson

When two nuclei collide at high energies there is a very strong interaction and many complicated reactions take place. The nuclei can excite each other and exchange a few nucleons before separating again, or they can fuse together for a short while to form a compound system that decays by emission of nucleons and alpha particles. At higher energies a nuclear shock wave can develop (*Nature*, **258**, 570; 1975) and this surges rapidly through the nucleus and causes the emission of a spray of nuclear fragments.

Some progress has already been made in understanding these reactions using the classical concepts of viscosity and the mechanics of shock waves, but further progress requires a more detailed quantum-mechanical treatment. The motion of the nuclei must be described in terms of the coordinates of their constituent nucleons by wavefunctions satisfying the Schrodinger equation.

Many theories of nuclear structure have now been developed that treat the motion of the constituent nucleons in this way, in particular the Hartree–Fock self-consistent field theory. This gives a series of coupled equations for the nucleon wavefunctions that can be solved in principle to give the single-particle wavefunctions and all the properties that can be derived therefrom. This is a very complicated calculation that can only be carried out in practice by making several simplifying approximations.

But the problem of understanding a nuclear collision in a similar way is immensely more complicated, essentially because it is dynamic. Although a time-dependent Hartree–Fock theory has been developed, it is difficult to apply it to nuclear collisions.

Faced with such a complicated problem, the best way to proceed is to make a simple model that, it is hoped, contains many of its main features, but is practicable to solve. Comparison between the solutions of the simple problem and the experimental data will then indicate the usefulness of the model, and possibly suggest ways of improving it. At the same time increasing familiarity with the mathematical structure of the simple solution may make it easier to see how the model can be made more realistic without at the same time making it impossible to solve.

This approach has recently been used by Bonche, Koonin and Negele (*Phys. Rev.*, **13**, 1226; 1976) in a first attempt to make a quantum-mechanical theory of the energetic interactions of heavy ions. To make the calculations tractable, they made very drastic assumptions, and yet rather surprisingly the results showed many of the features of the experimental data and thus encourage the development of the theory in more detail.

The first great simplification was to assume that the whole interaction essentially takes place in one dimension. They thus considered the collision of two slabs of nuclear matter having a specified thickness in their direction of motion but extending indefinitely in the directions at right angles. They also assumed that these slabs were completely symmetric in spin and isospin.

The Hartree–Fock theory requires the interaction between two nucleons, and this is known to be very complicated. They therefore constructed a simplified form of the interaction that contains most of the physics and adjusted its parameters to give the best overall agreement with nuclear properties.

In its full generality, the time-dependent Hartree–Fock theory gives a set of coupled non-linear integro-differential equations in three dimensions for the wavefunctions of the nucleons. After making the above approximations they reduce to a set of coupled linear equations that are readily solved by existing electronic computer techniques.

These equations were solved for a series of different initial conditions. They first of all studied the oscillations of a single slab, and found that these could take place at certain definite frequencies. These oscillations correspond to the collective 'breathing mode' oscillations of nuclei, that is oscillations without change of shape. The frequencies of such oscillations depend on the nuclear compressibility (see *Nature*, **254**, 480; 1975).

Next they found out how a slab interacts with a potential, and in particular how it is affected by passing through a potential barrier. At a speed $E/A = 10$ MeV and barrier of Gaussian form and height equal to the incident kinetic energy there is hardly any reflection, and the transmitted slab has a different density profile showing that it is in an excited state. The excitation consists of density ripples moving through the slab, and calculations show that 36% of the incident kinetic energy is converted into such excitations. This behaviour is markedly different from that of a single particle encountering a barrier at comparable energies: in that case only half the incident wave is transmitted and half is reflected. This comparison shows the importance of collective effects in the slab interaction; the attractive single-particle potential due to the other nucleons moving through the barrier reduces the effective potential and hence favours transmission over reflection.

As the barrier height is increased, so is the proportion of the slab that is reflected, until when the barrier is twice the incident kinetic energy it reaches 71%. In addition, the transmitted and reflected portions each split up into two pieces, one slowly moving and the other rapidly moving.

These studies are a useful preliminary to the main object of the calculations, namely to calculate the interaction of two nuclei, here represented by two slabs. At low energies ($E/A \approx 0.5$ MeV) the slabs fuse together to form a compound slab of rather uniform density that continues to oscillate without breaking up (see *Nature*, **261**, 193; 1976).

At a somewhat higher energy ($E/A \approx 3.5$ MeV) the compound slab is formed and then almost immediately separates again. Each fragment is oscillating strongly after the interaction, showing that it is highly excited. This process corresponds to the deep inelastic scattering of heavy ions, when two nuclei are strongly excited in a collision but essentially retain their identity, apart perhaps from the exchange of a few nucleons (see *Nature*, **256**, 261; 1975).

At much higher energies ($E/A = 25$ MeV) some quite new phenomena appear. As shown in Fig. 1, a region of very high density is formed, and from this region shock waves propagate outwards in both directions: these are indicated by the waves moving outwards at velocities higher than the incident slabs. When these waves of higher density reach the surface of the slab they separate from it, forming separate fragments that propagate rapidly outwards. Secondary waves follow them, and the region of almost uniform density that is formed for a short time in the central region breaks up from both ends into separate waves that also travel outwards and separate when they reach the surface, until eventually the whole compound system has broken up into fragments. Thus the model shows very well the phenomena of shock waves and fragmentation that take place in very energetic nuclear collisions.

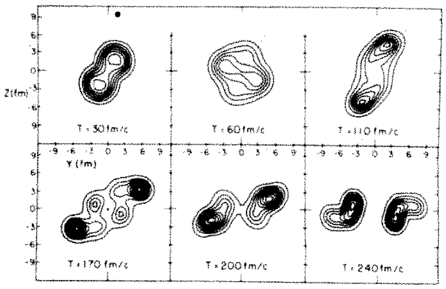


Fig. 2 Contours of the nuclear density for the collision of ^{16}O with ^{16}O at $E/A = 24$ MeV and an impact parameter of 4 fm. The contours are in the scattering plane and the density is integrated over the co-ordinate perpendicular to it.

An important advance has recently been made by Gusson, Smith and Maruhn (*Phys. Rev. Lett.*, **36**, 1166; 1976) in the form of a time-dependent Hartree–Fock (TDHF) calculation of the reaction $^{16}O + ^{16}O$ in three dimensions. The TDHF model they used assumes that the time-dependent wave function is given by a single Slater determinant whose occupied single-particle orbits obey the TDHF Schrodinger equation. For the interaction between the particles they used a simplified form of the Skyrme interaction, and assumed spin and isospin saturation, so that the spatial wave function applies to alpha particles.

Some of their results are shown in Figure 2, which gives the contours of the densities of the two interacting ions at various times in the plane of the collision, integrated over the direction perpendicular to that plane. The time scale is in units of fm/c, that is, about 3×10^{-24} s so the whole interaction takes about 10^{-21} s. These contour plots show that when a collision takes place at an impact parameter equal to about half the radius of the ions the outer regions interact strongly and stick the ions together in a dumb-bell shape which rotates about its centre of mass. As the system rotates, complicated internal motions take place, some parts rotating more rapidly than others. At one stage ($T = 170$ fm/c) small regions of higher density corresponding to alpha particles form in the region between the main mass concentrations. These are later attracted back and a neck forms between the two ions. The neck narrows and finally breaks, and the particles separate. They are now irregular in shape, indicating that they have been highly excited by the collision.

At no time in this interaction are high densities observed, indicating that the energy is too low for compression and shock wave phenomena to develop.

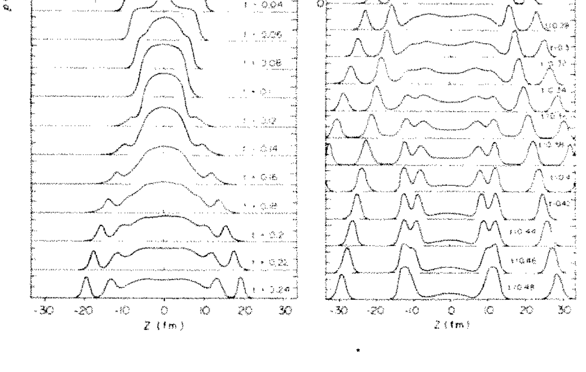

Fig. 1 Density profiles at various times t for the collisions of two slabs at a velocity corresponding to $E/A = 25$ MeV, showing the formation of a shock wave that propagates rapidly outwards, followed by a general fragmentation. (Times in units of 10^{-21} s.)

New data on the lower Palaeozoic sequence of northern Victoria Land, Antarctica, and its significance for Australian–Antarctic relations in the Palaeozoic

M. G. Laird & R. A. Cooper
New Zealand Geological Survey, Lower Hutt, New Zealand

J. B. Jago
South Australian Institute of Technology, North Terrace, Adelaide, South Australia

*New stratigraphical and palaeontological data from the Early Palaeozoic Bowers Group of northern Victoria Land indicates that its depositional basin was probably closely linked with the Dundas Trough of western Tasmania. On the **basis of these data, a revised reassembly of the Australo-** Antarctic portion of Gondwanaland is proposed.*

NORTHERN Victoria Land is a critical element in the reconstruction of the south-western Pacific sector of Gondwanaland. Most recent reconstructions of this sector have been based either largely on morphological best fits of continental margins[1–6] or on 'plate tectonic' reconstructions, that is, by 'reversing' seafloor spreading using a mapped pattern of magnetic lineations and fracture zones[7–11]. Only superficial attention has generally been given to the geology of the areas thus juxtaposed, primarily because of the lack of precise data from Antarctica.

Detailed evidence of distinctive structural–sedimentary belts that cross the Antarctic continental margin and thus serve as potential 'geological ties' has been singularly lacking, although broad correlation of Early Palaeozoic sequences has been attempted[2–4,7,12].

This note presents new stratigraphical, sedimentological and palaeontological data from northern Victoria Land which are inferred to provide such a tie in the Cambrian–Ordovician, linking the Bowers Group depocentre in Antarctica with the Dundas Trough of Tasmania. Data from Lower Palaeozoic sequences elsewhere in Antarctica and from the Adelaide Geosyncline support a continental reassembly constructed on this basis, and further suggest that Cambrian sedimentation in this segment of Gondwanaland may have occurred in separate eastern and western belts of contrasting environment. It seems that the widely accepted 'computer fit' of Australia and Antarctica[1] is unlikely to hold, at least during the early Palaeozoic.

Bowers Group sequence, northern Victoria Land

All known Lower Palaeozoic sedimentary rocks of northern Victoria Land are included within the Bowers Group[13], which lies within a 20–25-km wide infaulted belt extending south-east from near the mouth of Rennick Glacier for at least 270 km. To the north-east the Bowers Group rocks are inferred to be faulted against sediments of the Robertson Bay Group of probable Late Precambrian age[14]; and to the south-west they are faulted against metamorphic rocks of the Precambrian Wilson Group.

The oldest of the three units comprising the Bowers Group is the Sledgers Formation, a dominantly marine sequence whose base is not exposed. The formation, of minimum thickness 3,000 m, consists of mainly angular unsorted basaltic breccia containing common fragments of pillow lava, and a few thin flow units in the north; to the south it interfingers with dark mudstone containing thin interbedded rippled fine sandstone and lenticular turbidite units of graded coarse volcanogenic sandstone and conglomerate[15]. The sequence has yielded no age-diagnostic shelly fossils.

Overlying the Sledgers Formation without apparent discordance is the Mariner Formation, a fossiliferous marine sequence comprising sandstone at the base and passing upwards into shale with thin limestone and sandstone beds. The youngest beds of the Mariner Formation are red sandstone and mudstone with dessication cracks, rare inarticulate brachiopods and abundant trace fossils, including *Rusophycus* and *Cruziana*. This part of the sequence has been inferred[16] to represent a marine regression, the youngest beds representing an intertidal environment. Shelly fossils (trilobites and brachiopds) are relatively common throughout the Mariner Formation, the basal beds being of late Middle Cambrian age (*Ptychagnostus nathorsti* Zone or *Lejopyge laevigata* Zone) and the youngest fossils being of middle or late Late Cambrian age. At the southernmost limits of known exposure the formation is at least 1,600 m thick, but in the north of the mapped area, where the upper beds have been removed by Late Cambrian erosion, it is only 100 m thick.

A regional unconformity truncates the Mariner Formation, the overlying fluvial deposits of the youngest unit of the Bowers Group resting with marked erosion but no apparent angular discordance on middle to late Late Cambrian intertidal deposits in the upper Mariner Glacier region, and in places with marked discordance on early Late Cambrian marine mudstone 170 km to the north[17]. This youngest unit is exposed in two separate strips forming the eastern and western margins of the Bowers Group outcrop. In the eastern strip at least 3,000 m of red–brown or yellow quartzose sandstone, with minor quartzose conglomerate and mudstone (Camp Ridge Quartzite) is exposed in the core of a major syncline. The sequence is dominantly fluvial and lacks body fossils, although locally near the base trace fossils including *Rusophycus*, *Daedalus*, *Monocraterion*, and *Skolithos* occur[14]. In the western strip of outcrop, mainly fluvial deposits of minimum thickness 800 m dominated by conglomerate (Carryer Conglomerate) occupy a similar stratigraphic position unconformably above fossiliferous marine beds[15].

Late Cambrian and Early Ordovician granitic rocks crop out extensively to the west of the Bowers Group, but none are known to intrude it. Post-tectonic granitic plutons of Devonian to Early Carboniferous age (Admiralty Intrusives) intrude both the Robertson Bay and Bowers Groups. This igneous province is restricted to the area east of the Rennick Glacier, and is thought by some writers to be associated with tectonic movements (Borchgrevink Orogeny) which resulted in folding of both sedimentary groups[13,18].

Dundas Trough Sequence, Tasmania

The main locus of Cambrian sedimentation in Tasmania (the Dundas and Fossey Mountain Troughs) lay between the Precambrian Rocky Cape and Tyennan crustal blocks and the Forth Nucleus, forming an arcuate belt around the northern and western margins of the Tyennan Geanticline[19,20]. The axial portion of the Dundas Trough contains two main marine sedimentary sequences separated by an inferred unconformity[21]. The older sequence, which contains no shelly fossils, consists of greywacke, siltstone, shale and quartzite with some interbedded mafic volcanics (Crimson Creek Argillite, Success Creek Group, and correlatives[22–24]). Ultramafic complexes are found associated with these older rocks at several localities within the Dundas Trough, but are not known to intrude the fossiliferous Cambrian sequences.

The younger sequence comprises turbidite greywacke, siltstone, shale and conglomerate (Dundas Group and correlatives). It contains fossils (mainly trilobites) at several horizons; the oldest beds are Middle Cambrian (*Ptychagnostus gibbus* Zone) whereas the youngest beds range in age from early Late Cambrian (*Mindyallan* Stage) in the north[25], to late Late Cambrian (*Ptychaspis-Prosaukia* Zone) in the south.

Sediments of Middle to Late Cambrian age were also deposited in the Smithton Basin to the north-west of the Rocky Cape Geanticline[20], in the Dial Range Trough (a northern extension of the main Dundas Trough), and in the Adamsfield Trough to the east of the Tyennan Geanticline[26,27].

Along the eastern margin of the Dundas Trough, adjacent to the Tyennan Precambrian block is an arcuate belt of acid to intermediate volcanic rocks and associated sediments—the Mount Read Volcanic Arc. Rocks of the lower part of the sequence (Queenstown Pyroclastics, Central Lava Belt and Intrusives) grade westwards into greywackes of the Dundas Trough. The upper part of the sequence (Tyndall Group) unconformably overlies the lower part and is composed of tuff, agglomerate, sandstone and conglomerate; fossils of late Middle or early Late Cambrian age indicate that the Tyndall Group is, at least in part, of equivalent age to the Dundas Group to the west.

The Cambrian Dundas Group and Tyndall Group sediments are both unconformably overlain by the Owen Conglomerate or its equivalent, representing the basal unit of the Junee Group[21]. This contact marks a conspicuous change in lithology and sedimentation. The Cambrian units are predominantly of the siltstone–greywacke–greywacke conglomerate association, whereas the Owen Conglomerate and its equivalents are quartz- and chert-rich sandstone and conglomerate. Fossils of early Ordovician age are known from the middle part of the Junee Group and the unfossiliferous basal beds are likely to be of late Cambrian or earliest Ordovician age. Along the axis of the Dundas Trough contact between conglomerate and underlying beds is generally paraconformable[25]; however, successively younger beds underlie the contact from north to south, so that at Birch Inlet—the most southerly sequence—only a short break in sedimentation is inferred, whereas in the Dial Range Trough in the north, most of the late Cambrian is missing[25]. Near the northern margin of the Tyennan Geanticline three small granitic plutons of probable Late Cambrian age[28] intrude Cambrian and older rocks.

Shallow water platform sedimentation continued over much of eastern Tasmania from Ordovician to Early Devonian times without notable interruption until a widespread period of deformation between the Early and Late Middle Devonian, known as the Tabberabberan Orogeny, affected all the Early Palaeozoic rocks of the area. The Orogeny was accompanied and followed by granitic intrusions.

Cambrian sequences elsewhere

In Victoria, widely scattered outcrops contain sparsely fossiliferous Middle and Upper Cambrian shale and sandstone overlying an unfossiliferous sequence of spilites and cherts[29]. Unlike the intensively studied Ordovician, however, the Cambrian sequences are poorly exposed and the stratigraphic relationships not sufficiently well known to be discussed in detail here.

In South Australia Early Cambrian rocks rest disconformably on Late Precambrian sediments in the main area of sedimentation, the Adelaide Geosyncline[30]. The Lower Cambrian is characterised by a thick succession of shallow water shales and archaeocyathine-bearing carbonates. Extrusive igneous rocks are limited to a few small areas of basic to intermediate volcanics in the southern part of the Adelaide Geosyncline[31], and some thin tuffaceous horizons within the Cambrian sediments of the Flinders Ranges[32]. In the late Early Cambrian, uplift led to erosion of older Cambrian sediments in the Yorke Peninsula area and the formation of conglomerates on both Yorke Peninsula and Kangaroo Island[32]. Widespread carbonate deposition at the beginning of the Middle Cambrian was followed by red-bed deposition which may have extended up into the Late Cambrian in much of the Adelaide Geosyncline, including Yorke Peninsula[32], as fossiliferous late Middle and Upper Cambrian sediments are known from the Frome Embayment and the Warburton Basin further to the north.

In the Kanmantoo Trough, lying to the east of the Adelaide Geosyncline, a thick succession of metasediments (Kanmantoo Group) conformably overlies fossiliferous Early Cambrian sediments (Normanville Group). An inarticulate brachiopod, *Lingulella*, is found near the base of the Kanmantoo Group; however, with this exception, worm burrows are the only fossils known. The clear-cut contact between the Normanville and Kanmantoo Groups indicates the start of a new depositional cycle which was triggered by the Kangarooian Movements. These movements which affected the Fleurieu Peninsula, Kangaroo Island and Yorke Peninsula areas, lasted at least into the Middle Cambrian[33]. Late Cambrian and Early Ordovician granites intrude the Kanmantoo Group in several places, thus placing a maximum age range of Early to Late Cambrian on its time of deposition. Other granites of similar age are found in southern South Australia. A folding movement (Delamerian Orogeny) took place in the Late Cambrian–Early Ordovician[34].

In Antarctica, the nearest known fossiliferous Cambrian sediments to those in northern Victoria Land lie 1,000 km to the south in the region between the Nimrod and Byrd Glaciers. Here the Byrd Group[35] comprises over 8,000 m of limestones with minor shale, sandstone, quartzite, and conglomerate unconformably overlying Late Precambrian metasediments. Archaeocyathinae occur sporadically throughout most of the sequence, but have been positively dated only from immediately north of the Nimrod Glacier. Here a small collection from beds within 1,000 m to 1,300 m of the base of the Group belong to the Lower Lena Stage (late Early Cambrian)[36]. The stratigraphically highest Archaeocyathinae occur at least 6,500 m above the base of the Byrd Group, and are likely to be early Middle Cambrian.

South of the Nimrod Glacier widely separated outcrops of mixed clastic and carbonate sediments containing fossils of Early and Middle Cambrian age occur in the Shackleton Glacier[37] and Leverett Glacier[38] areas respectively. North of the Byrd Glacier, in south Victoria Land, scattered areas of unfossiliferous but probably in part Cambrian mixed carbonate–clastic sequences are also known[39]. No further outcrops of calcareous rocks correlatable with the Early and Middle Cambrian Byrd Group occur between south Victoria Land and the northern coast, but a hint that the archaeocyathine limestone belt, now eroded or covered by ice, may once have extended as far north as the coast west of northern Victoria Land, is given by the record of marble erratics, one containing a possible Archaeocyathid, at Cape Denison[40] (Fig. 1).

Early Ordovician granitic rocks, which intrude the Byrd Group

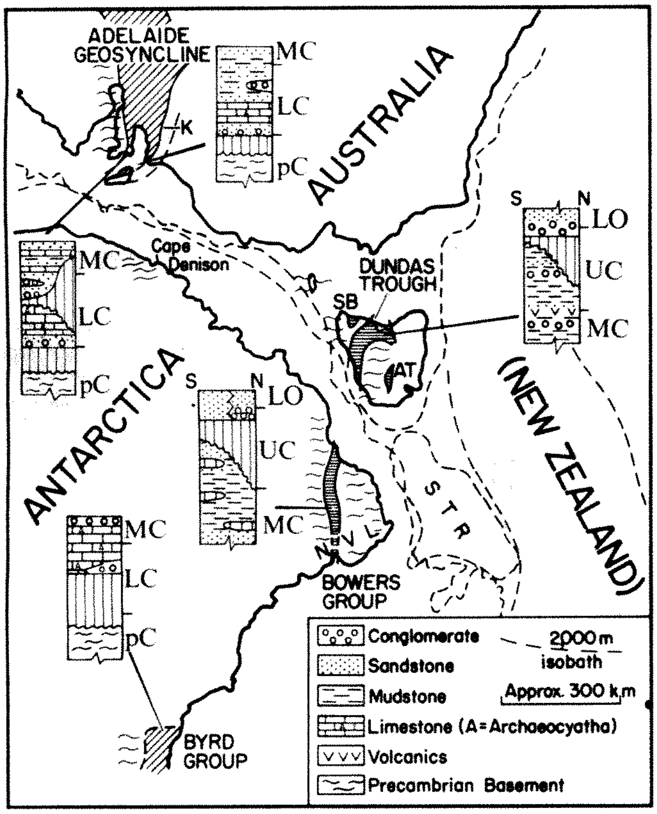

Fig. 1 Reconstruction of the south-eastern Australian and East Antarctic elements of Gondwanaland, showing the main Cambrian depositional sites (horizontally and obliquely hatched areas) and stratigraphic columns for critical successions. NVL, Northern Victoria Land; STR, South Tasman Rise; AT, Adamsfield Trough; K, Kanmantoo Trough; SB, Smithton Basin. Vertically hatched areas on the stratigraphic columns represent time gaps. Note: stratigraphic column for Dundas Trough is for the axial part, south to north, and thus does not include Mount Read Volcanics. The column for the Bowers Group similarly spans the belt from south to north. pC, Precambrian; LC, MC, UC, respectively Lower, Middle and Upper Cambrian; LO, Lower Ordovician.

south of the Nimrod Glacier[41], are widespread throughout the central Transantarctic Mountains and south Victoria Land. This intrusion of granites accompanied and followed a major tectonic movement, the Ross Orogeny, which was responsible for folding the Byrd Group and its probable correlatives.

Australia–Antarctica reassembly

Figure 1 shows comparative columns of the main elements of the stratigraphy and tectonics of the Cambrian sequences in Antarctica, South Australia, and Tasmania. A similarity is at once apparent between the northern Victoria Land (Bowers Group) and Tasmanian columns, constructed along the axial portions of both belts. The youngest fossiliferous marine deposits are in both cases overlain unconformably by dominantly continental coarse quartzose sandstones and conglomerates of probable latest Cambrian or earliest Ordovician age. They are both underlain by unfossiliferous clastic sequences with mafic volcanics; however, the volcanics form a major part of the Antarctic sequence but only a minor part of the Tasmanian succession. The Cambrian of both areas is intruded by Devonian–Carboniferous granites, in contrast to the other areas studied. Both successions were apparently deposited in rapidly subsiding trough-like structural depressions bounded by Precambrian blocks. Both regions were affected to a similar degree by tectonic activity particularly during latest Cambrian and Early Ordovician times, resulting in similar sequences of quartzose gravels and sands. It is likely, therefore, that western Tasmania lay very close to the Bowers Group depocentre in Cambrian and Early Ordovician times.

By contrast, fossiliferous Late Cambrian is absent from the southern South Australian sequences, while the Early and early Middle Cambrian, which appears to be almost fully represented, contains prominent archaeocyathinae limestone horizons. The contrast between the stratigraphy and geological history of the Cambrian of northern Victoria Land and that of South Australia shows that the sequences could never have been directly continuous, and the areas were unlikely to have been adjacent. However, a similarity is apparent between the archaeocyathine limestone-bearing Byrd Group of Antarctica and the South Australian sequences.

A reasonably firm geological basis for continental reconstruction between Australia and Antarctica has thus been established. The "geologic fit" proposed here (Fig. 1) differs markedly from the widely accepted "computer fit" based on morphology[1], but is relatively close to Griffith's "plate tectonic" reconstruction[7]. However, in this fit, Australia has been rotated anticlockwise slightly with respect to Antarctica so that the Cambrian of western Tasmania is nearly continuous with a possible northern extension of the Bowers Group. This reassembly has the added advantage of accommodating the South Tasman Rise with almost no overlap adjacent to the eastern coast of northern Victoria Land. The similarity of the quartzose semi-schist of the Rise with that of the Robertson Bay Group, and the coincidence of K/Ar age dates in both areas, has already been noted and correlation suggested by other workers[42]. It is interesting to note that the proposed fit, based on correlation of the Cambrian of western Tasmania and of northern Victoria Land, leaves the Archaeocyathine limestones of the Adelaide Geosyncline and of the Byrd Group in a position apparently far to the west of the projection of the Bowers Group–Dundas Trough alignment. This outcrop distribution could be accounted for by post-Cambrian strike-slip movement between Tasmania and mainland Australia causing segmentation of a once continuous but somewhat sinuous belt (as some writers[43–46] have suggested), or pair of belts. An alternative possibility (rendered particularly attractive if Mawson's reported discovery[40] of a possible Archaeocyathid in marble erratics at Cape Denison represents the northern extension of the Byrd Group) is that Cambrian sedimentation occurred in two distinct belts, the Early and Middle Cambrian Archaeocyathid-bearing one lying parallel to but well to the west of the Bowers Group–Dundas Trough depocentre. If the latter interpretation is valid, the necessity for major strike-slip movements between Tasmania and mainland Australia is eliminated.

The general similarity between the Cambrian fit proposed here and Palaeocene reassemblies of Antarctica and Australia based on "reversal" of seafloor spreading[7, 8] is highly significant, implying that the relationship of the western Ross Sea sector of Antarctica to Tasmania and possibly to the whole of south-eastern Australia was substantially the same in the Cambrian and in the Palaeocene.

We thank Drs P. Andrews, J. Bradshaw, B. Daily, G. Grindley, and D. Skinner for discussions and for reading the manuscript. The work in northern Victoria Land was carried out by the writers in conjunction with D. I. MacKinnon, J. E. Simes, J. D. Bradshaw and A. Wodzicki during the 1974/75 austral summer as part of the New Zealand Antarctic Research Program, and is associated with IGCP Project 7 "South-west Pacific Basement Correlation".

Received October 11; accepted November 11, 1976.

Preliminary findings of the Viking gas exchange experiment and a model for Martian surface chemistry

V. I. Oyama, B. J. Berdahl & G. C. Carle

National Aeronautics and Space Administration, Ames Research Center, Planetary Exploration Office, Moffett Field, CA 94035

Oxygen and CO_2 were evolved from humidified Martian soil in the gas exchange experiment on Viking Lander 1. Small changes in N_2 gas were recorded. A model of the morphology and a hypothesis of the mechanistics of the Martian surface are proposed.

THE early results from the gas exchange experiment (GEX), on Viking Lander 1 have already been reported but were limited to preliminary findings only[1]. This paper examines the findings and interprets them in terms of a model of the soil surface morphology and chemistry.

All major GEX activities that occurred after landing up to the end of the first incubation cycle are given in Table 1. In Table 2 are listed the sample processing and transport environments to which the soil was subjected up to the point when the first analysis was made; they may have relevance to the extent and nature of the gaseous responses.

Data on instrument performance will be reported at a later date. Descriptions of the concepts governing the design of the experiment, modes of operation and results obtained are described elsewhere[2–7].

Humid mode results

The first incubation cycle began with the addition of 1 cm^3 Martian soil to the 8.7 cm^3 test cell (0.465 $cm^3 \pm 0.035$ cm^3 solid volume, estimation based upon solid density range of 2.6–3.0 $g\,cm^{-3}$ for the soil in the test cell and a bulk density of 1.3 $g\,cm^{-3}$) (Viking Physical Properties Team). In the process of loading the soil and sealing the test cell, Martian atmosphere was trapped within the chamber at the prevailing pressure of 7.6 mbar (ref 8). A 0.132 cm^3 volume of starting gas at 8.394 atm consisting of 5.51% Kr, 2.84% CO_2, and 91.65% He

Table 1 Major events in the first cycle of the gas exchange experiment

Event	Date (Sol)*	Elapsed time from landing (s)
Landing	0	0
Initiate chromatographic column rejuvenation	2	206,156
Soil sample added to test cell	8	682,426
Seal test cell	8	683,439
Add incubation gas, Kr/CO_2/He	9	759,219
Inject 0.57 ml nutrient (humid mode)	9	759,879
First headspace gas analysis (humid)	9	769,876
Second analysis	10	860,176
Third analysis	11	948,916
Fourth analysis	13	1,126,756
Fifth analysis	15	1,302,556
Inject 2.3 ml nutrient (wet mode)	16	1,383,339
First headspace gas analysis (wet)	16	1,392,916
Second analysis	17	1,481,656
Third analysis	18	1,570,456
Fourth analysis	20	1,744,456
Fifth analysis	25	2,189,320
Sixth analysis	28	2,446,105

The column rejuvenation cycle is the process by which the gas chromatograph columns, which have been opened to the vacuum of space, are cured of the need to be primed for oxygen in order to make quantitative measurements of oxygen in any given sample. The test cell had two positions on the carousel: the first to receive sample and the second to be sealed against the head-end. The latter contained all the attachments for adding gases and nutrient and for removing sample from the headspace. The soil was contained in a porous cup suspended over a sump that allows drainage, when required, and variable additions to either humidify or wet the soil. Test cell volume empty was 8.7 cm^3 and the sample loop volume was 0.1114 cm^3. The amount of gas lost by sampling varied as a function of the total pressure in the test cell, the relative sample loop and headspace volumes and the gas distributions which were a function of temperature and gaseous species.

*Sol (the Martian day) is 24 h, 39 min, 35 s long.

Table 2 Soil sample history

Location	Temperature (K)	Time duration (h)
Soil surface (0–5 cm deep)	190–208	N.A.
Collection head (collect then dump)	204–206	0.09
Arrival at Biology PDA (soil processor) through shuttle (dump from PDA to SDA)	239–280	0.26
Arrival at Biology SDA (soil distribution) through soil dump to test cell	280–282	0.05
Arrival of soil in test cell through seal of test cell	282	0.28
Seal of test cell through humidification (addition of 0.57 ml nutrient)	282	21.2
Humidification through first analysis	282	2.78

Soil temperature estimated, all other temperatures directly measured.

and 0.567 cm^3 of M4 nutrient[3] were added to the lower cavity of the test cell, an amount insufficient to wet the soil but providing 100% relative humidity. The final pressure in the test cell after the above additions is estimated to be 150 mbar. Results of the first and subsequent gas chromatographic analyses of the headspace gases during the humid mode are shown in Table 3. After analyses of the headspace, the total gases in the test cell were estimated from Ostwald coefficients for aqueous solutions[9–14] to determine the contribution of the gases dissolved in the liquid phase. The results were corrected for the initial contributions of the original trapped Martian atmosphere[15], the starting Kr/CO$_2$/He gases and Ne introduced by the nutrient injection and losses from sampling the headspace gas. Solution coefficients were used for CO$_2$ to correct for the estimated basicity of the soil (Table 3). This technique was used only for CO$_2$ to approximate the magnitude of the CO$_2$ change.

The results show the CO$_2$, O$_2$, N$_2$ and Ar and/or CO (the Ar and CO are not resolved by this gas chromatograph) were evolved by the soil sample. The maximum amount of N$_2$, 83 nmol, appeared on Sol 11 (Sol is a Martian day, equal to 24 h, 39 min and 35 s) and decreased to 77 nmol by Sol 15. Oxygen, on the other hand, after reaching its maximum on Sol 11, appears to have reached a plateau. From the assumed total oxidation of ascorbate in the M4 nutrient[3], the net amount of O$_2$ produced equals 775 nmol (690 plus the 85 associated with the oxidation of ascorbate). The maximum amount of CO$_2$ attained occured on Sol 13 and was approximately, 9,800 nmol. This decreased on Sol 15 to 9,400 nanomoles. No conclusion on the presence or change of CO can be made because of the low values of the combined Ar/CO peak. The values in Tables 3 and 4 of Ne and Kr demonstrate the consitency of the internal standards and the apparent precision for the gas analyses.

Wet mode results

On Sol 16, additional (estimated volume = 2.268 cm^3) M4 nutrient was injected. With the amount added earlier, the nutrient, now measuring 2.835 cm^3, wetted the soil. The results for the wet mode are shown in Table 4. The level of N$_2$ monotonically rose for an increase of 11 nmol whereas in the humid mode we had seen an increase followed by a decrease in the N$_2$ content.

Oxygen monotonically decreased from the plateau that was attained at the end of the humid mode and reached a minimum. The total amount of O$_2$ consumed equalised 325 nmol which is 78% of the ascorbate-oxygen equivalence added.

With water now making contact with the soil, the gaseous content of the interstitial water could be estimated. For the 1 cm^3 soil amount, an estimate of 5–50 µm particle sizes (personal communication from H. J. Moore, Viking Physical Properties Team) yielded an interstitial soil–water volume of about 35% (ref. 16). This value was used to estimate the total CO$_2$ in the solution contacting the soil, as separated from the CO$_2$ in the larger volume of water in the test cell sump that was treated separately as if it were unaffected by the soil. The interstitial soil solution and solution in the sump compartment shared a common headspace atmosphere from which the CO$_2$ was measured. The calculations show that CO$_2$ estimates are only meaningful to the extent that they represent a minimum.

During the entire first cycle, no H$_2$, NO or CH$_4$ was observed in the headspace.

Model for Martian surface chemistry

From very preliminary laboratory data (personal communication from Dr Edward Merek, Ames Research Center) using terrestrial volcanic ash, it was observed that some of the CO$_2$ adsorbed at Martian surface temperatures, 190–268 K, was desorbed at the higher incubation temperature of the test cell,

Table 3 Gas composition (corrected) in gas exchange test cell (humid mode)

	Time from humidification (h)				
	2.78	27.86	52.51	101.91	150.74
	Mars Date				
	Sol 9	Sol 10	Sol 11	Sol 13	Sol 15
Gas	Quantity of gas* (nmol)				
N$_2$	73	76	83	79	77
O$_2$	500	650	690	690	690
CO$_2$	5,900	8,300	9,500	9,800	9,400
Ar†	8	7	13	9	8
Ne‡	20	19	18	20	21
Kr§	2,000	2,000	2,000	2,000	2,000

*The gas chromatograph detector data were sampled at 1 s intervals, digitised and fitted to a skewed gaussian distribution from which peak heights were obtained. The gas in the headspace was obtained from the ratio of the sample loop volume to the total headspace. The cumulative gas composition was corrected for sampling losses by referencing absolute changes in the krypton values for successive samples. Corrections were made for pressure sensitivity in this flight instrument caused by a partial restriction in the gas sampling system which prevented total evacuation of the sample loop to ambient pressure before filling (three times) from the test cell. The volume for krypton was corrected for pressure as follows:

$$\text{nmol Kr} = 37.77\,(P_c)\exp\,-0.118\,(V_p)\exp\,1.016$$

where P_c is the test cell pressure in mbar, V_p is the peak height in volts. The value for each gas was corrected by the ratio of the term 37.77 $(P_c)\exp\,-0.118$ to the similar Kr value from a pressure-insensitive instrument. P_c was determined from an inventory of all sources of pressure such as the enclosed atmosphere, the pressure of the initialisation gas injected and any additional injections of helium required to increase cell pressure. The gas composition as stated was corrected by removal of contributions from known sources (for example trace contaminants in injected gases) and for the amount dissolved in the liquid phase. An estimate of dissolved gases was made from literature values for the Ostwald coefficients. The effects of pH on the CO$_2$ distribution were included by estimating changes in apparent CO$_2$ levels upon nutrient injections in LR (second injection) and upon the wet-mode nutrient injection in gas exchange. The relationship used was

$$\frac{\text{(nanomoles, dissolved)}}{\text{(nanomoles, gas phase)}} = L\,\frac{\text{(volume, liquid)}}{\text{(volume, gas)}}$$

where the L values for CO$_2$ are as follows. Sol 9 and 10: $L = 21.4$; Sol 11–15: $L = 28.4$; Sol 16: $L = 40.4$; Sol 17–28: $L = 68.5$. The data shown in this table and in Table 4 are revised from those given in ref. 1 by better values for the atmospheric composition and the composition of the krypton/carbon dioxide gas. The correction, subtracting these contributions from the total, tend to increase the values, but do not alter the conclusions reached.

†Assumed to be argon (argon is not resolved from carbon monoxide on this column).

‡Mean value for neon = 20.02±1.09 (±5.44%).

§Mean value for krypton = 1,975±0 (±0%).

281–283 K, during the first 21.23 h that the soil was sealed in the test cell. However, when the same volcanic ash was then humidified, major desorption of the CO_2 occured in 2.78 h. When the amount of CO_2 desorbed was related to the Martian soil, the 9,800 nmol of CO_2 reduced to 0.33 mg CO_2 desorbed per g soil. This value of desorbed CO_2 which is assumed to be adsorbed by Martian soil is within the model proposed by Fanale and Cannon[17] and supports the method we used to estimate total CO_2. The CO_2 production in the wet mode was probably due to oxidation of nutrient organic compounds.

Table 4 Gas composition (corrected) in gas exchange test call (wet mode)

	Time from 2.3 ml nutrient injection (h)					
	2.66	27.31	51.98	100.31	223.88	295.21
	Mars date					
	Sol 16	Sol 17	Sol 18	Sol 20	Sol 25	Sol 28
Gas	Quantity of gas (nmol)					
N_2	76	78	78	79	86	87
O_2	670	600	550	510	460	450
CO_2	9,600	11,000	12,000	13,000	13,000	12,000
Ar	8	8	7	8	9	8
Ne	100	150	160	170	170	180
Kr	2,000	2,000	2,000	2,000	2,000	2,000

See Table 3 for details of test and calculations.

The unexpected amount of O_2 accompanying the desorption of CO_2, 9,800 nmol/775 nmol (13 : 1 CO_2/O_2) from the minimum 270 : 1 CO_2/O_2 ratio in the Martian atmosphere[15] represents an oxygen enrichment of approximately 20 times in the Martian soil. It is improbable that the excess amounts of O_2 found beyond that expected from adsorption of atmospheric O_2 comes from the direct or biological photocatalysis of water or hydroxyl groups, for the reasons that the critical temperature for O_2 is too low for adsorption in the quantities needed and the diffusion rate of O_2 at 7.6 mbar is too rapid to allow for enrichment to occur. A more likely source for the O_2 is chemically bound oxygen which is stable at GEX cell temperatures but allows displacement of oxygen by water. The surface of the grains of rock or mineral are good sources for this chemically bound oxygen. A simple estimate of the surface area of the grains can be made to assess whether all of the oxygen can be accommodated. The surface area of the grains are assumed to be 400–2,000 cm^2 per cm^3 of soil (personal communication from H. J. Moore for 5–50-μm particle sizes). Assuming 33.4 $Å^2$ coverage per molecule, a monolayer of O_2 covers 1,560 cm^2, and is accommodated by the available grain surface. The requirement that chemical absorption cannot extend beyond a monomolecular layer[26] is pertinent.

A model of surficial materials which can accommodate both oxygen and CO_2 is solid silicate particles covered with fine iron oxide particles. The carbon dioxide desorbed from a monolayer would be accommodated on 19,710 cm^2 of the iron oxide surface (assuming the 33.4 $Å^2$ for CO_2 also). The iron oxide cover would be approximately three particles deep, under the conservative assumption that each iron oxide particle is a cube that has six times the surface area of the rock surface it covers. The least surface area is obviously a sphere having four cross sectional diameters of surface for each area of the mineral it would cover. If the mean particle size in the atmosphere (2 μm diameter) (ref. 19) is indicative of the iron oxide diameters on the surface, the mean thickness of the three-layer iron oxide is 6 μm. This is thick enough to make the inner surface opaque to the solar ultraviolet, but also too thick to be consistent with $\leqslant 2$ μm thickness reported by the Inorganic Chemical Analysis Team (ICAT) on the limits of iron oxide coating allowed for measurement of underlying silicate surfaces[18]. If the value of the particle sizes were closer to the lower conservative estimate of 0.2 μm (ref. 20), the mean thickness would be compatible with the ICAT limit of detection.

These estimates of surface area are preliminary best estimates and may be revised at a future date. Lunar fines[25] have surface areas near 5×10^3 cm^2 g^{-1} while clays[16] have surface areas in the range of 10^5–10^7 cm^2 g^{-1}. The results of the GEX may ultimately yield an estimate of the surface area of the Martian surface materials.

The mechanical structuring of the oxygen affixed to the inner mineral surface instead of on the outer iron oxide coat is consistent with known chemicals, alkali and alkaline earth metal peroxides and superoxides that are capable of producing both O_2 and H_2O_2 in the presence of water vapour[21]. A candidate for one of the metal superoxides is calcium because of calcium's apparent abundance in the Martian soil[18]. For each superoxide hydrolysed by water, an equivalent alkaline site is produced that accounts for the resorption of the desorbed CO_2. But in the natural state, the basicity of the inner surface is not transferred to the iron oxide coat, because the mineral surface is mechanically separated at the molecular level from the iron oxide coating of several layers. The H_2O_2 formed from superoxide hydrolysis will, in the presence of abundant iron oxide catalyst, directly participate in the oxidation of the exact number of oxidisable equivalents such as formate in the Labelled release (LR) nutrient[22] or GEX M4 nutrient[3]. The alkali and alkaline earth metal superoxides are only one of many examples of the proposed chemistry on a stoichiometric basis that can well be applied to the ozonides, perchlorates, permanganates, and so on.

The iron oxide external surfaces provide at low temperature a monomolecular layer of adsorbed CO_2 which when activated by the solar ultraviolet flux splits off nascent oxygen and CO. The latter is free to return to the atmosphere. At higher temperatures, ultraviolet catalysis is limited by the quantity of CO_2 adsorbed. Other sources of nascent oxygen are photochemically formed ozone and hydrogen peroxide which are catalytically decomposed by the surficial iron oxide to form O_2 and O and H_2O and O, respectively. Then ascent oxygen, by simple diffusion (albeit an inefficient process, but time is not of the essence) passes through the porous iron-oxide matrix and attacks the inner mineral surface where it reacts with alkali and alkaline earth metal oxides to form the hydroxy-peroxides, superoxides, peroxyradicals and/or ozonides, if it does not first recombine with CO or react with another nascent oxygen. On the inner mineral surface, the products of the nascent oxygen reaction remain relatively stable but are potentially vigorous oxidisers.

If the oxygen–soil model is correct, it implies that the oxidiser source is distributed generally throughout the entire soil sample bed, that is, through the entire depth of the trench dug on the first sample taken. On the other hand, if the activity were associated only with the surface, there would have to be ten times the activity from just the surface material. If the red colour is associated with this activity, the colour photographic data substantiate that the entire trench is the same as the surface (personal communication from T. A. Mutch, Viking Lander Imaging Team). Furthermore, only a small fraction of the actual surface material is probably represented in the soil sample acquired. For example, a simple test of the surface sampler at JPL on surface tinted soil shows that only 11% of sieve size material 1.5 mm $> d >$ 0.589 mm, 9% of 0.589 mm $> d >$ 0.495 mm and 3% of 0.495 mm $> d$ are of surface origin in the test sample. A distribution of the oxidative capability throughout the entire depth of the trench, not just located on the exposed surface, indicates a history of stability consistent with the concept of the protective iron oxide coat under which is buried the oxygen-producing source. The stability is contrary to having the oxygen coupled surficially on the iron oxide coat because it would be at the mercy of transient changes in the vaporous environment over extremely long periods of time.

Another aspect of the iron oxide coating which bears on the stability question is related to the weak acidic nature of this material. Qualities which are ascribed to acid-like surfaces are the following: the ready emission of CO_2 from the soil in GEX, the small first peak from the pyrolytic release experiment (PR), the initial instant release of $^{14}CO_2$ from the LR and the higher background counts when LR was cooled following heating of the test cell to sterilisation temperatures[1]. The significance of the LR sterilisation regime is that the temperature is sufficient to volatilise such materials as $H_2SO_4 \cdot 2H_2O$ (boiling point 169°C) which can coat surfaces and prevent readsorption of $^{14}CO_2$ at the LR test cell temperature. The latter observation provided us with a basis for speculating that surficial acidity is provided by a thin coat of sulphuric acid from sulphate salts of weak bases (amorphous sulphate). A probable source of this sulphate is SO_3 produced by the visible activity of the past[23]. The SO_3 reacts with any water vapour in the atmosphere to produce sulphuric acid that descends as a mist to cover the iron oxide coat. Such hygroscopic coatings could well preserve the integrity of the highly active inner superoxide coat during episodes of higher water vapour incidences on Mars while explaining durable O_2 production from the soil sample in the test cell. It may explain the observed cohesive nature of the Martian soil. The acid characteristic of the surface ascribed to amorphous sulphate is born out by the high level of sulphur measured by the ICAT (ref. 18) and the oxidised state of the surface as evidenced by the red colouration of the iron oxide outer coat. The acidic surficial characteristics are quickly neutralised by the strongly basic alkali and alkaline earth metal hydroxides formed by the hydrolytic reaction as demonstrated by both GEX and LR.

The above model of the silicate mineral covered with iron oxide requires that ultraviolet light initiate the process of nascent production where adsorbed CO_2 and/or H_2O is concentrated on the surface of the iron oxide particles. To maintain a steady-state concentration of these energy-rich oxygen bonds on the inner mineral surface, the combined dissipative effects of water vapour and heat must be counterbalanced by an equivalent influx of nascent oxygen. When temperatures are low and water vapour is virtually limited, as appears to be the case in the Lander 1 area, the oxygen sources are prevalent. Sites having more water vapour are expected to have less active material and produce less oxygen, but it remains to be determined whether the effective oxidative capacity, that is the capability to oxidise organics, is also reduced. The H_2O_2 product (unstable in the presence of iron oxide) may remain uncontacted by the iron-oxide outer coat.

The degree to which the particle surfaces are re-exposed to the ultraviolet flux to renew the activity, the penetration of nascent oxygen, hydrogen peroxide and/or ozone downward through the soil bed and the concentration of water vapour are factors that must be considered fully to describe and/or predict the potential to produce oxidisers at any site for any depth into the surface of Mars.

At the Viking Lander 1 site, the vista is an ancient one where the soil was formed before the boulders were strewn over it. This suggests that the soil was layered over fluvial scoured rocks well after the episodes of water formed the surface. The oxidisers could have been created by two distinctly different processes. During a period when there was a dense atmosphere, silicate particles could have been lifted into the atmosphere by winds allowing the surfaces to be exposed to solar ultraviolet thus creating oxidisers which have been preserved to this date. Oxidisers could also be formed constantly at a rate through the entire soil bed from atmospheric hydrogen peroxide, ozone or nascent oxygen providing a steady state production of oxidiser which counters the dissipative effects of warmth and humidity. Both ozone and hydrogen peroxide can provide nascent oxygen in our model.

The oxidisers in the Martian soil are good candidates for the reaction observed in the LR experiment[1] as well as some of the observed CO_2 evolution in GEX. They must have the requisite qualities of oxidising the formate in the LR, producing the O_2 in GEX and accounting for some of the CO_2 released in GEX. A reaction that could account for the above observations starts with 534 nmol of the metal superoxide, $M(O_2)_2$:

$$586H_2O + 534M(O_2)_2 \rightarrow 775O_2 + 534M(OH)_2 + 52H_2O_2$$

Thermodynamic calculations proving the validity of these types of reactions in the environment simulating GEX will be tested at a later date.

Thee quivalent amount of oxidiser in the LR (26 nmol per 0.5 ml soil) calculated by one of us (V.I.O.), indicates that the inferred H_2O_2 produced as a result of soil reacting with water is limiting.

Because of the large abundance of water with respect to formate in the LR (ref. 22), 55.56 M per 2.4×10^{-4} M $\sim 2.3 \times 10^5$ l^{-1}, and in the GEX 1.9×10^5 l^{-1}, it is unlikely that the superoxide will oxidise the formate directly, but will provide the requisite H_2O_2 in the reaction with water.

In the GEX, the N_2 changes are small and can be explained from either initial N_2 desorption from soil by water vapour and subsequent resorption in liquid water or biological fixation, while N_2 production could arise from a Van Slyke reaction where α-amino nitrogen in the M4 nutrient reacts on the aforementioned external-acid surfaces with nitrite in Martian soil. Since N_2 exists in the Martian atmosphere and there is postulated NO in the upper atmosphere[24], it would not be inconsistent to assume oxides of nitrogen exist in the Martian soil.

As we have observed from our studies of lunar soils[6,7], metallic iron formed by meteoric bombardment of lunar iron oxides provides a basis for estimating the biologically important, free-water history of a planet. At this time, no H_2 has been found, therefore no metallic iron can be inferred in the Martian sample tested by GEX. This suggests that an amount of water and/or O_2 necessary to oxidise the metallic iron to the depth of the regolith was available at some time for this oxidation. For answers on the question of the state of oxidation of the planetary surface as measured by the presence of metallic iron, we must await the recharge occurring at the start of the second cycle to remove O_2 so as to measure the production of H_2 from the oxidation of Fe° by H_2O, and await the findings of Lander 2. The ultimate sensitivity for H_2 detection will allow us to measure 0.003% of metallic iron in the Martian soil if O_2 is not present in the test cell.

The advantage of starting with metallic iron as a precursor source of iron oxide is that it presents iron in an easily oxidisable form that allows the propagation of the iron oxide product on a broad planetary scale without the need for liquid water. Only water vapour and O_2 are required. The early development of the iron oxide in the history of Mars explains how the dry lubricating qualities of the iron oxide dampens aeolian erosion and removes the need for liquid water to extrude iron oxide deposits from their sources.

We prepared earlier for an expected chemistry of an arid planet[3] and must await the dissipation before life can be determined. At this time, all of the gas changes we have observed in our GEX test cell can be explained most easily by mechanistic processes. Although these results and explanations are preliminary, we find no need to invoke biological processes. While continued careful study is required, it is anticipated that results from Viking Lander 2 will reinforce our conclusions.

This work was done under contract to the National Aeronautics and Space Administration Viking Project Office. We thank M. Lehwalt, E. Merek, M. Rowland, S. Chang, S. Fong, N. Gee, J. Griffin and R. Mendoza of NASA-Ames Research Center for contributions; R. Day, S. Jeanjaquet, F. Brown, R. Gilje, S. Loer, J. Katherler, G. Rosiak and D. McMorris and all the unnamed participants at the TRW Systems Group who helped design, fabricate, test and nurture the GEX; H. Klein, J. Lederberg, A. Rich, J. Hubbard and R. Johnson for their advice; G. Soffen, C. Broome, G. Lee and T. Young for their interest in the GEX; T. Mutch and M. Carr, P. Toulmin, II, H. Moore and R. Hargreaves for their specific contributions in picture interpretations, inorganic analysis, physical properties and magnetics, respectively; C. Reichwein, and D. Buchendahl especially, for development of software specifically for GEX and for precise knowledge of the Viking System, respectively, and finally D. DeVincenxi for encouragement and continued Division support.

Storage of elastic strain energy in muscle and other tissues

R. McN. Alexander

Department of Pure and Applied Zoology, University of Leeds, LS2 9JT, UK

H. C. Bennet-Clark*

Department of Zoology, University of Edinburgh, EH9 3JT, UK

Storage of strain energy in elastic materials has important roles in mammal running, insect jumping and insect flight. The elastic materials involved include muscle in every case, but only in insect flight is the proportion of the energy stored in the muscle substantial.

MUSCLE has elastic properties and so do the tendons and skeletal elements to which muscles attach. These properties are exploited by animals in two main ways. First, energy is saved, in insect flight and in mammal running, by storing elastic strain energy at one stage in the wingbeat or stride and releasing it at another[1-3]. Second, some insects have catapult mechanisms which enable them to jump much higher than they otherwise could[4]. We have assessed the relative importance of the elastic properties of the muscles and of other structures in each of these activities. The arguments which follow show that the role of the elastic properties of the muscles is trivial in mammal running and insect jumping, but may be important in insect flight.

Capacity for elastic storage

Huxley and Simmons[5] investigated the elastic properties of active frog semitendinosus muscle. They compensated for the compliance of the tendons by a spot-follower device so that they measured only the compliance of the muscle fibres themselves. Their observations indicated that elastic extension occurs almost exclusively in the crossbridges. Each active crossbridge is stretched by 15 nm. The experiments of Jewell and Wilkie[6] with intact muscles indicated rather less stretching than this but those of Rack and Westbury[7] indicated that the crossbridges were stretched by about 30 nm.

Consider a muscle fibre of length l, sarcomere length λ exerting a force P. Let each crossbridge suffer an elastic extension b so that each sarcomere extends $2b$. The fibre as a whole extends $2bl/\lambda$ and the elastic strain energy U is $P/2$ times this

$$U = Pbl/\lambda \qquad (1)$$

Let the mass of the fibre be m and its density ρ so that its volume is m/ρ and its cross-sectional area $m/\rho l$. The stress σ in the fibre is given by

$$\sigma = P\rho l/m \qquad (2)$$

From equations (1) and (2) the strain energy per unit mass of muscle is

$$U/m = \sigma b/\lambda\rho \qquad (3)$$

Let the maximum stress which can be developed in isometric contraction be σ_0, and the corresponding strain energy U_0.

We have calculated values of U_0/m for various muscles, assuming that active crossbridges stretch 15–30 nm in the invertebrate muscles as well as in vertebrate striated muscle (Table 1). The values of U_0/m are all fairly similar because σ_0 is likely to be roughly proportional to λ[13].

The maximum work which can be done by a muscle in a single contraction is the area under a graph of isometric force against length. From Fig. 1 this can be shown to be 220 J kg^{-1} for frog striated muscle and 420 J kg^{-1} for a crayfish muscle with longer sarcomeres. Notice that these values are of the order of 100 times greater than the capacity of muscle for storing elastic strain energy.

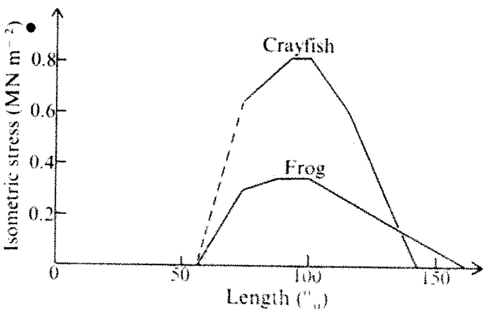

Fig. 1 Graphs of isometric stress against muscle fibre length for frog semitendinosus[8,15] and crayfish extensor carpopoditi[16]. Length is expressed as a percentage of the length at which the isometric stress is maximal.

---

*Present address: Department of Zoology, University of Oxford, UK

Now consider a muscle in series with a tendon of length l_t. When it exerts a force P it stretches the tendon by Δl_t and the elastic strain energy stored in the tendon is

$$U_t = \tfrac{1}{2}P\Delta l_t \qquad (4)$$

This can be expressed as a multiple of the elastic strain energy in the muscle, which is given by equation (1)

$$U_t/U = (\lambda/2b)(\Delta l_t/l) \qquad (5)$$

$\lambda/2b$ is 35–70 for vertebrate striated muscle and rather more for some insect muscles (Table 1). Tendons stretch about 10% (ref. 14) and insect apodemes about 3% before breaking[12]. Δl_t may thus be almost 0.1 l_t for tendons and 0.03 l_t for apodemes, if they are not much thicker than they have to be to withstand the forces their muscles exert on them. Hence U_t/U is likely to be greater than l_t/l. Pennate muscles with short fibres and long tendons or apodemes (that is, with large values of l_t/l) are likely to store far more elastic strain energy in their tendons or apodemes than in their muscle fibres.

Running

When a rubber ball bounces it loses kinetic energy and then regains most of it. The energy is stored briefly as elastic strain energy and converted back to kinetic energy in the rebound. Similarly a running mammal loses and regains kinetic and potential energy in every step. Some of this energy is stored as elastic strain energy in muscles and tendons and restored in an elastic recoil. The rest has to be replaced by metabolic work. Measurements of the oxygen consumption of running men and hopping kangaroos indicate that as much as 50% of the energy which would otherwise be needed for locomotion may be saved in each case by elastic storage[2,3].

Table 1 Strain energy stored in the series elastic component of various muscles in isometric contraction, calculated by equation (3) assuming a density of 1,060 kg m^{-3}

Muscle	Vertebrate striated	Locust flight	Hemipteran flight	Locust leg
Sarcomere length, λ (μm)	2.1	3.9	2.6	8.5
Maximum isometric stress, σ_0 (kN m^{-2})	350	350?	120	800
Strain energy U_0/m (J kg^{-1}) for:				
b = 15 nm	2.4	1.3	0.7	1.3
b = 30 nm	4.7	2.5	1.3	2.7
Reference	8	9	10, 11	12

The only leg muscles which can save energy in this way are the ones which first extend and then shorten while their foot is on the ground. The extensors of the ankle do this and so do the extensors of the knee (except in wallabies) but the other major leg muscles do not[3,17]. The extensors of the ankle and knee are pennate with long tendons, the Achilles and patellar tendons. Table 2 shows that far less elastic strain energy is stored in muscle fibres than in the Achilles tendon, in running men, hopping wallabies and jumping dogs. Strain energy has been calculated for the ankle and knee extensor muscles together, but for the Achilles tendon alone. We have not enough data to make reliable estimates of the elastic strain energy stored in the patellar tendon, but it is plainly substantial. The discrepancy between the quantities of strain enregy stored in the muscles and tendons must be even more marked than is apparent from Table 2.

The data for man is less reliable than the other data in Table 2. The value for muscle mass m was obtained from a dissecting-room cadaver (albeit an unusually robust one) and is almost certainly less than the mass of the corresponding muscles in the men who made the force-platform records. If so, the stress σ in the muscles will have been overestimated so the value of U (which is proportional to $m\sigma$, equation (3)) is probably about right.

Insects jumping

A boy using a catapult does work relatively slowly on the rubber, storing elastic strain energy which is released very rapidly in the elastic recoil. The power output of the catapult is thus much greater than the power input: the catapult serves as a power amplifier. Elastic structures are used in the same way by jumping insects. They are needed for the following reason.

Suppose an animal has muscles which, like vertebrate striated muscle, can do work amounting to 220 J kg^{-1} in a single contraction. Suppose that the jumping muscles make up 5% of the mass of the body. They are in principle capable of giving the body 11 J kinetic energy per kg body mass, that is of accelerating it to a take-off velocity of 4.7 m s^{-1} which is enough for a vertical jump in which the centre of mass rises 1.1 m. This is true, whatever the size of the animal. However, a small animal must accelerate to its take-off velocity over a very short distance, in a standing jump: it must give itself the kinetic energy in a very short time so the power output required (per unit mass of muscle) is high. Locusts take off at 3.2 m s^{-1} or less and the jumping muscles make up 7.5% of body mass so the work the muscles have to do is only 70 J kg^{-1}. However, the power required is 5,000 W per kg muscle, about ten times the maximum power output of the fastest known muscle[19]. Locusts and other jumping insects can only jump as well as they do because they have catapult mechanisms. Their leg muscles contract, storing elastic strain energy in themselves, their apodemes and other structures. This energy is released very rapidly at take-off, by a trigger mechanism.

Nearly all the energy for a locust jump is supplied by the extensor tibiae muscles. Table 1 shows that the elastic strain energy stored in these muscles before a jump is unlikely to be more than 2.5 J kg^{-1}, a very small fraction of the 70 J kg^{-1}

Table 2 Calculations of elastic strain energy in the muscles and in the Achilles tendon of one leg of a man running at 3.9 m s^{-1}, a wallaby (*Protemnodon rufogrisea*) hopping at 2.4 m s^{-1} and a dog taking off for a running long jump

	Man	Wallaby	Dog
Mass of animal (kg)	68	10.5	26
Mass of muscles, m (kg)	1.66	0.48	0.37
Muscle strain energy, U (J)	4.1–8.3	0.36–0.73	0.6–1.1
Force in tendon, P (N)	4,700	850	2,000
Extension of tendon, Δl_t (mm)	18	11	25
Tendon strain energy, U_t (J)	42	4.7	25
Reference	18	3	14

The muscles referred to are the extensors of the ankle and knee. The strain energy in them has been calculated from equation (3), using the stresses calculated in the references and the values of b and λ given in Table 1. The extensions of Achilles tendon in the wallaby and dog have been taken from references 3 and 14; the value for man has been calculated in the same way, assuming a cross-sectional area of 70 mm^2. The strain energy in the tendon has been calculated by equation (4).

which is needed. The rest is apparently stored as elastic strain energy in the apodemes of the muscles and in the semilunar processes of the knee joint[12].

Similar conclusions can be drawn from our knowledge of jumping by fleas and click beetles. The kinetic energy at take-off is around 20 J per kg muscle and 60–100 J per kg muscle for strong jumps by the flea *Spilopsyllus* and the beetle *Athous*, respectively[20,21]. Only a little of this can be stored as elastic strain energy in the muscles. Most of it is stored in other structures, in fleas mainly in pads of the elastic protein resilin.

Table 3 Assessment of the contribution of elastic strain energy in muscles to jumping by locusts and fleas

	Locust	Flea
Length of muscle fibre (mm)	4	0.3
Fractional shortening required, ε	0.23	0.11–0.20
Sarcomere length (μm)	8.5	5
Expected elastic strain, ε′	0.007	0.012
$\frac{\text{Muscle strain energy}}{\text{Total work}}$, $\frac{\varepsilon'}{\varepsilon}$	0.03	0.06–0.11
Reference	12	20,32

The geometry of the legs requires the muscle fibres to shorten by the fraction ε, to extend the legs at take off. If each crossbridge stretches by 30 nm the elastic strain of the muscle fibres will be ε′.

Table 3 confirms the conclusions of the past few paragraphs. It shows by a different argument that elastic strain energy in the muscles can contribute very little to jumping by locusts and fleas.

Insect flight

The role of elastic storage in insect flight is very like its role in running. Kinetic energy taken from the wings at the end of one stroke is stored as elastic strain energy and used in the next stroke. As much as 50% of the power which would otherwise be needed for flight may be saved by elastic storage[1,22].

The flight muscles of locusts in level flight deliver 170 W kg^{-1} (ref. 23). The frequency of the wing beat is 19 Hz so the work done by the muscles in each contraction is 9 J kg^{-1}. As much as 2.5 J kg^{-1} may be stored as elastic strain energy in their fibres (Table 1) depending on the stress which is developed. Larger quantities of elastic strain energy are stored in cuticular structures (mainly in structures made of resilin, ref. 24) but the contribution of muscle elasticity cannot be neglected. Many insects beat their wings at much higher frequencies but their muscles deliver little or no more power[22] so the work per cycle is much less and the possible contribution of muscle elasticity correspondingly more important. Many of them have myogenic muscles which shorten between 1% (in *Bombus*) and 3% (in *Calliphora*)[25]. In such muscles, the sarcomeres are around 2.5 μm long, so if the crosslinks can strain elastically by 30 nm, elastic strains of 2.2% are possible.

In oscillatory contraction these muscles exert greater forces during the shortening half cycle than during the lengthening half cycle. A graph of force against length (or of moment against wing angle, Fig. 2*a*) is a loop of which the area represents the work done in each cycle. The gradient of the long axis of the loop is the elastic stiffness of the muscle and approximately corresponds to the graph of force against length for the active muscle in the non-oscillatory condition.

The power output of such muscles is high. The output of flight muscles of the beetle *Oryctes* is 30 W kg^{-1} (at about 40 Hz) and for *Bombus* muscle (at a higher frequency) 60 W kg^{-1}, both measured *in vitro*[26]. Estimates based on the metabolic rate and the probable efficiency of muscle suggest that bees and flies may be able to produce muscle power outputs in the order of 200 W kg^{-1} (calculated from data of Weis-Fogh, in ref. 26). As the muscle seems to be able to store up to 1.3 J kg^{-1} (Table 1), it seems that at the quite moderate frequency—for a small insect with myogenic muscles—of 100 Hz, the muscle could store and release 130 W kg^{-1} which is of the same order as the active power output. The muscles should thus act as major stores to conserve the kinetic energy of the wings and as such should bring about harmonic oscillation of the wings.

It is unfortunate for this argument that simple harmonic oscillation of the wings rarely occurs (see ref. 27). It is usual to find that the angular velocity of the wing is fairly constant during both up and down strokes and that the wing direction changes abruptly at the extremes of the stoke[28,29]. This cannot be explained by the simple harmonic motion of an elastic oscillating flight motor.

One mechanism which causes this is the dipteran click mechanism[30]. The click mechanism in isolation acts in a manner similar to an electric light switch; at the two extremes of the travel, the mechanism is stable and the wing sets either top dead centre or bottom dead centre. When moved but a short distance from the extreme position, the wing when released snaps back to the extreme position but when moved beyond its midpoint, the wing continues to move until it clicks into the other extreme position. Depending on the geometry of the system, the mechanism can have a greater or lesser effect on the wing movement.

Figure 2*c* is a schematic graph showing the moment exerted by the click mechanism at different wing angles. Muscle elasticity tends to restore the wings to their mid position but the click mechanism acts in opposition to it, tending to send the wings to one or other extreme position. The click mechanism does not absorb energy (Fig. 2*c* shows a line, not a loop) but in the middle part of the stroke it stores elastic energy while the muscles are releasing elastic energy and vice versa. Figure 2*d* shows how the forces exerted by the click mechanism probably affect the other forces which act on the wing. They reduce or eliminate the inertia force in the middle section of the stroke so the wing accelerates early in the stroke, moves at fairly constant velocity in the middle part of the stroke and decelerates again at the end.

The click mechanism has other functions. It brings about the rapid torsional movements of pronation at the start of the downstroke and of supination at the bottom of the downstroke[27,30], which are utilised in the clap-fling and flip mechanisms of lift generation proposed by Weis-Fogh[22]. The energy

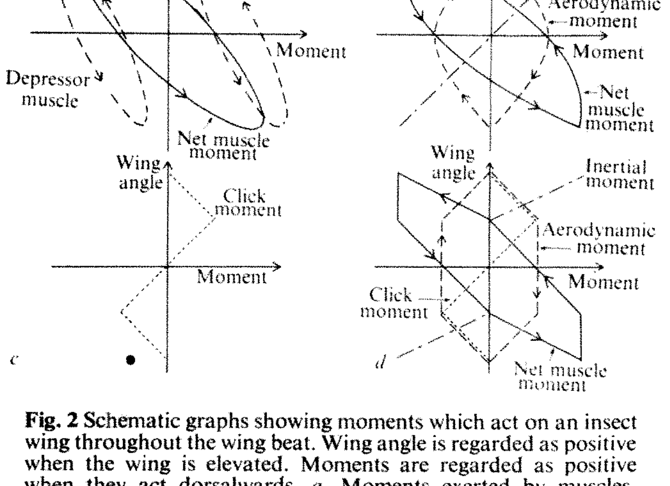

Fig. 2 Schematic graphs showing moments which act on an insect wing throughout the wing beat. Wing angle is regarded as positive when the wing is elevated. Moments are regarded as positive when they act dorsalwards. *a*, Moments exerted by muscles. The moments exerted by the levator and depressor muscles can be added together to give the net muscle moment. *b*, Moments on a wing which has no click mechanism. The moments shown must total zero at all stages in the wingbeat cycle. Inertial moment is shown proportional to wing angle, implying simple harmonic motion. *c*, Moments exerted by the dipteran click mechanism. *d*, Moments on a wing with a click mechanism. The moments shown must total zero at all stages in the wing beat. Readers will observe that the schematic graphs of net muscle moment in *a*, *b*, and *d* differ a little in shape. We do not know the precise shape of the loop for any intact insect and have obtained the shapes shown by making simple assumptions about the shapes of the graphs of other moments.

for these rapid movements is derived from the energy produced by the flight motor and the resultant kinetic energy of rotation of the wings, which is absorbed at the extremes of the wing stroke by the click mechanism and returned as rapid angular acceleration and torsional rotation of the wing. Thus the click mechanism acts as both a skeletal energy store and a power amplifier. Furthermore, since conventional cuticle can store 0.5–2 kJ kg^{-1} (ref. 31), the mass of the click mechanism may be as little as 1% of that of the flight muscles.

Role of series elastic component in locomotion

The series elastic component of muscle operates over small strains. Hence it can only store a small part of the work done by a muscle which shortens by a large fraction of its length. Also, it can only be responsible for a small part of the total store of elastic strain energy if the muscle is in series with a long compliant tendon. For these reasons it is relatively unimportant in insect jumping and mammal running. However, it is probably important in myogenic insect flight muscles, which operate over very small strains.

The quantity of elastic strain energy which can be stored in unit mass of material is 5 J kg^{-1} or less for muscle (Table 1) but it is 2,000–9,000 J kg^{-1} for tendon collagen, insect apodeme and resilin[4]. A structure for storing elastic strain energy can be much smaller if it is made of one of these latter materials than if it is made of muscle. The amount of work which can be done by a muscle in a single contraction may be 400 J kg^{-1} or more (Fig. 1) so a muscle designed to do a given amount of work will be far too small to store a similar amount of elastic strain energy. Hence the capacity of muscles for storing elastic strain energy is generally too small to be useful.

Insect flight muscles operate over very small strains so they do very little work in each contraction. However, they could not be replaced by smaller muscles working over larger strains because the power output required of them (around 200 W kg^{-1}) is apparently close to the maximum available from muscle[19]. Their capacity for elastic storage is large enough to be extremely useful. In general, the elastic strain energy to be stored in each cycle of wing movement is similar in quantity to the net work done by the muscles[22]. If the wing frequency is 20 Hz and the power output of the muscles 200 W kg^{-1}, the work done in each cycle is 10 J kg^{-1} and the capacity of the muscles for storing elastic strain energy may need supplementation. If the frequency is 200 Hz the work done per cycle (for the same power output) is only 1 J kg^{-1} and the capacity for storing strain energy may be ample even when partially counteracted by a click mechanism. Large insects such as locusts fly with low wingbeat frequencies and have structures such as relatively large resilin pads to supplement the elastic storage capacity of their muscles. Dipteran flies, being smaller, have higher wingbeat frequencies, and use click mechanisms which partly counteract the elastic compliance of the muscles. Their resilin hinges are relatively small.

Storage of elastic strain energy in muscles (or in tendons or apodemes in series with muscles) must imply an energy cost, since energy is needed to develop and maintain tension in muscle. We are unable to assess this cost for any of the activities we have discussed, but note that it will be least with slow muscles where storage is brief relative to the cycling time of the crossbridges.

DNA base sequence of the $p_{\rm O}$ promoter region of phage λ

G. Scherer, G. Hobom & H. Kössel

Institut für Biologie III der Universität Freiburg, 78 Freiburg I. Br., FRG

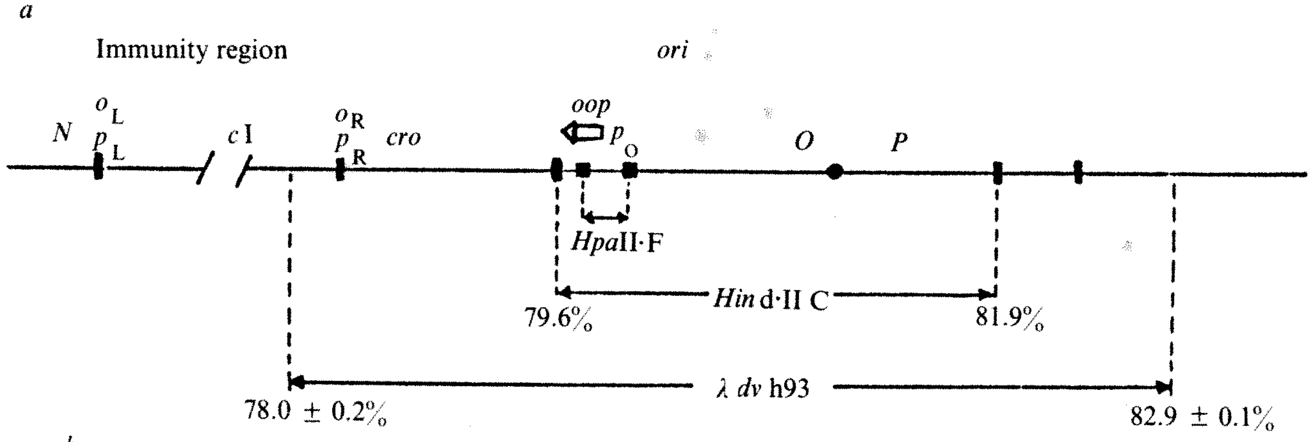
The sequence of a 123 base pair HpaII restriction fragment of bacteriophage λ DNA has been determined by the dimethylsulphate–hydrazine technique. Of this fragment 65 nucleotide pairs are transcribed into the 5′ proximal part of the oop RNA. The remaining 58 nucleotide pairs preceding the start point of transcription show homologies to the $\lambda p_{\rm L}$ *and* $\lambda p_{\rm R}$ *promoter regions, and are concluded to contain the* $\lambda p_{\rm O}$ *promoter sequence.*

REPLICATION of bacteriophage λ DNA proceeds bidirectionally[1] starting from a well defined region positioned between 79.9 and 80.6% on the λ physical map[2]. All known *cis*-dominant mutants affecting the origin of replication (*ori*) map within this region[3-6]. A small RNA molecule of known sequence[7] is transcribed from the *l* strand of this DNA segment (79.9–81.1) (ref. 8), and there is evidence that this RNA acts as a primer in the initiation of λ DNA replication[9]. Both the synthesis of this *oop* RNA, and the initiation of λ DNA replication require the products of the phage genes *O* and *P* as well as the *dna*B and the *dna*G gene products of the host[9,10]. In addition, mRNA synthesis initiated in this area has been shown to be involved in transcription leading to repressor establishment during lysogenisation[11]. This suggests that the *oop* RNA may be equivalent to a mRNA leader transcript. Because of this role in lysogenisation, phage gene *c*II and *c*III products may also modify initiation or attenuation[12] rates of the *oop* RNA synthesis.

As a step towards elucidating the structural features of this area in more detail we have undertaken to sequence the promoter region of the *oop* RNA. The 81-nucleotide sequence of the *oop* RNA as reported in ref. 7 contains a CCGG sequence at positions 68–71, which indicates a restriction enzyme *Hpa*II sensitive site[13] for the corresponding DNA sequence. Therefore, the generation of a restriction fragment of at least 70 base pairs could be expected with this enzyme. This fragment would represent the DNA complement of most of the *oop* RNA sequence and perhaps part or all of the p_O promoter region. In order to deal with a smaller number of *Hpa*II restriction fragments, we have used the small λ-derived plasmid λ*dv*h 93 (ref. 14) instead of DNA from the whole λ phage (see Fig. 1). Cleavage of λ*dv*h 93 DNA with *Hpa*II enzyme produces 10 major fragments, 7 of which have more than 70 base pairs (A to G, Fig. 1). For further selection among those *Hpa*II fragments, the fragment λ*dv*h 93–*Hin*dII·C (ref. 14) was isolated, since it spans the region where the *oop* RNA has been mapped (Fig. 1). Only four of the fragments with more than 70 base pairs were produced on digestion with enzyme *Hpa*II: fragments B, C, E and F (Fig. 1). Fragment T, which is not observed in the *Hpa*II digest of total λ*dv*h DNA, comprises the terminal portion of the *Hin*dII·C fragment that contains the terminator region of the *oop* RNA (E. Schwarz, unpublished work from this laboratory, and ref. 15). The decanucleotide d(T–G–G–A–T–C–T–A–T–C) whose sequence is complementary to the nucleotides 4–13 of the *oop* RNA sequence (see Fig. 4) had been synthesised chemically in our laboratory (D. Ghosal, unpublished). In a reaction catalysed by DNA polymerase I with linearised and denatured λ*dv*h 93 DNA as a template, this decanucleotide acts as a primer near the p_O promoter region. When the isolated and denatured *Hpa*II fragments B, C, E and F were tested in four parallel experiments as templates in such reactions, only the fragment *Hpa*II·F gave primer-dependent products (D. Ghosal, in preparation).

Sequence determination of the fragment *Hpa*II·F

For determination of the DNA sequence of the restriction fragment by use of the dimethylsulphate/hydrazine technique developed by W. Gilbert and A. Maxam, the fragment *Hpa*II F was first labelled at its 5′ ends using polynucleotide kinase and [λ-^{32}P]-ATP. As no internal restriction enzyme sensitive site was available for separating the two labelled 5′ ends, strand separation by electrophoresis on a 10% polyacrylamide gel[16] had to be performed (Fig. 2). In order to reduce cross contamination of the two strands, both were purified further by a second strand separation cycle. The dimethylsulphate–hydrazine technique (W. Gilbert and A. Maxam, personal communication, and ref. 17) consists of four parallel reactions, two of them being purine specific, with dimethylsulphate as a reagent, the other two being pyrimidine specific, using hydrazine. The products of the four limited (one random hit per chain) degradation reactions are fractionated according to chain lengths in adjacent slots on a denaturing polyacrylamide gel. The patterns of radioactive products are then made visible by autoradiography. The methylation conditions for the G and A specific reactions are identical, but the release of the methylated bases is different: neutral release at higher temperature (15 min at 90 °C) is more specific for the methylated G sites and results in a final gel pattern with heavy bands representing polynucleotides terminating at the G positions; only light bands are obtained from the A positions ('G-specific' reactions). Acid release (60 min at 0 °C in 0.1 N HCl) gives the opposite result, dark bands for every A position and light bands for every G position



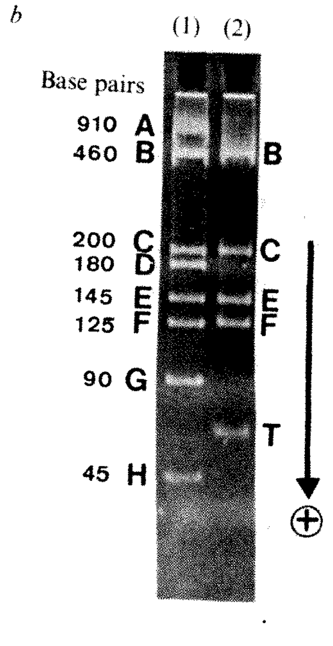


Fig. 1*a*, Physical and genetic map of the immunity and *ori* regions of phage λ. The position of the *Eco*RI cut (●) at 81.0% of the λ physical map[26] and of several *Hin*dII sites (▮)[14] are indicated, as well as the location of only two of the *Hpa*II cuts (■) generating the *Hpa*II·F fragment used in this work. The position of the small λ-derived plasmid λ*dv*h 93 (molecular weight 1.45 × 10^6) and of the *Hin*dII·C fragment are taken from ref. 14. For the designation of genes see ref. 27. p_O symbolises the promoter region for *oop* RNA synthesis. The map is drawn to scale. *b*, DNA fragment patterns obtained from *Hpa*II digests of λ*dv*h 93 DNA (1) and of the *Hin*dII·C fragment (2). The *Hpa*II (ref. 28) and *Hin*dII enzymes (ref. 29) were purified according to the methods of Smith and Wilcox[29]. λ*dv*h 93 DNA was prepared as described previously[14] and the *Hin*dII·C fragment was obtained by separating a *Hin*dII digest of λ*dv*h 93 DNA on a preparative 2% Agarose slab gel. The respective gel region was excised, crushed and extracted in NTE buffer (0.5 M NaCl, 0.1 M Tris-HCl, *p*H 8.0, 5 mM EDTA) at 30 °C for 2 d. Gel fragments were then removed by filtration through glass wool, and the extracted DNA was ethanol precipitated (2 volumes, 15 min at −70 °C), centrifuged at 10,000*g* for 20 min and resuspended in 1 mM Tris-HCl, *p*H 8.0. For the experiments shown in wells (1) and (2), incubations were carried out in 6.6 mM Tris-HCl, *p*H 7.5, 6.6 mM $MgCl_2$, 6.6 mM β-mercaptoethanol at 37 °C for 4 h and the material was then subjected to electrophoresis on a 10% polyacrylamide slab gel (20 cm × 30 cm × 0.2 cm) run in TBE-buffer (50 mM Tris borate, *p*H 8.3, 1 mM EDTA)[30]. After running the gel at room temperature for 13 h at 150 V, the bands were made visible by soaking the gel for 15 min in TBE-buffer containing 2 μg ethidium bromide ml^{-1}. The band patterns were then photographed under ultraviolet light. The numbers adjacent to the letters indicate the estimated numbers of base pairs of the respective fragments. The estimations were done by comparison with known restriction fragments of λ*dv* DNA (ref. 14).

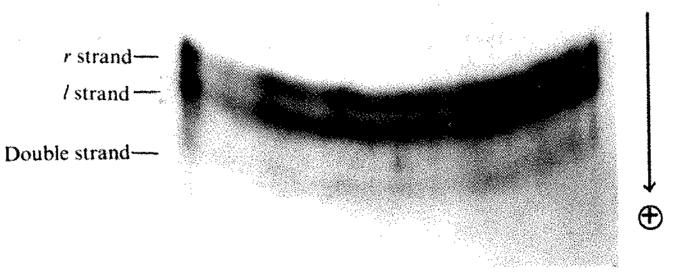

Fig. 2 DNA strand separation of fragment *Hpa*II·F. Preparative amounts of the restriction fragment *Hpa*II·F were obtained by cleaving 300 µg of λ*dv*h 93 DNA with enzyme *Hpa*II, separating the products on a preparative 10% polyacrylamide slab gel (20cm × 30 cm × 0.4cm) and extracting the fragment as described in Fig. 1. For the 5′-terminal labelling, about 10 pmol of fragment *Hpa*II·F were incubated with 0.2 units of alkaline phosphatase from calf intestine (grade I, Boehringer-Mannheim Biochemicals) in 10 mM Tris-HCl, *p*H 9.3 at 37 °C in a total volume of 40 µl. The reaction was stopped after 30 min by the addition of 8 µl of 50 mM EGTA and boiling the whole mixture in a sealed capillary for 3 min. 200 pmol of [γ^{32}-P]-ATP (prepared by the method given in ref. 31 with a specific activity of about 1,000 Ci mmol^{-1}) and 5–8 units of polynucleotide kinase (Boehringer-Mannheim Biochemicals) were added with 8 µl 10 × kinase buffer (0.4 M Tris-HCl, *p*H 9.3, 0.1 M $MgCl_2$, 10 mM DTE, 50% glycerol) and the reaction mixture (80 µl) was incubated for 30 min at 37 °C. After terminating the reaction with 10 µl of 0.5 M EDTA, the mixture was adjusted to 0.3 M sodium acetate. Ethanol precipitation was then carried out in the presence of 100 µg of carrier tRNA (2 volumes ethanol, 15 min at −70 °C). The dried pellet was resuspended in 300 µl of strand separation solution (10% glycerol, 0.3 N NaOH, 1 mM EDTA) according to W. Gilbert and A. Maxam (personal communication) and loaded on a 10% polyacrylamide slab gel in a sample well of 8.5 cm × 0.4 cm. The gel was run in TBE-buffer at 4 °C and 300 V, until the xylene cyanol FF marker applied in a separate well had reached the bottom of the gel (30 cm). X-ray film (Agfa Gevaert Osray T4) was exposed for 30 min to the gel covered with polyethylene wrap. Under the conditions given, the *r* and *l* strands (at 20.0 and 20.8 cm from the origin) were clearly separated. The small band seen below the separated strands represents undenatured (or renatured) double-stranded DNA. The regions containing the separated strands were cut out and extracted twice with 2 ml each of NTE buffer at 30 °C for two 24 h periods; this led to about 90% recovery of radioactivity. On running a second strand separation cycle (not shown) the final yields ranged between 1 × 10^5–2 × 10^5 c.p.m. per strand, as measured by Čerenkov radiation.

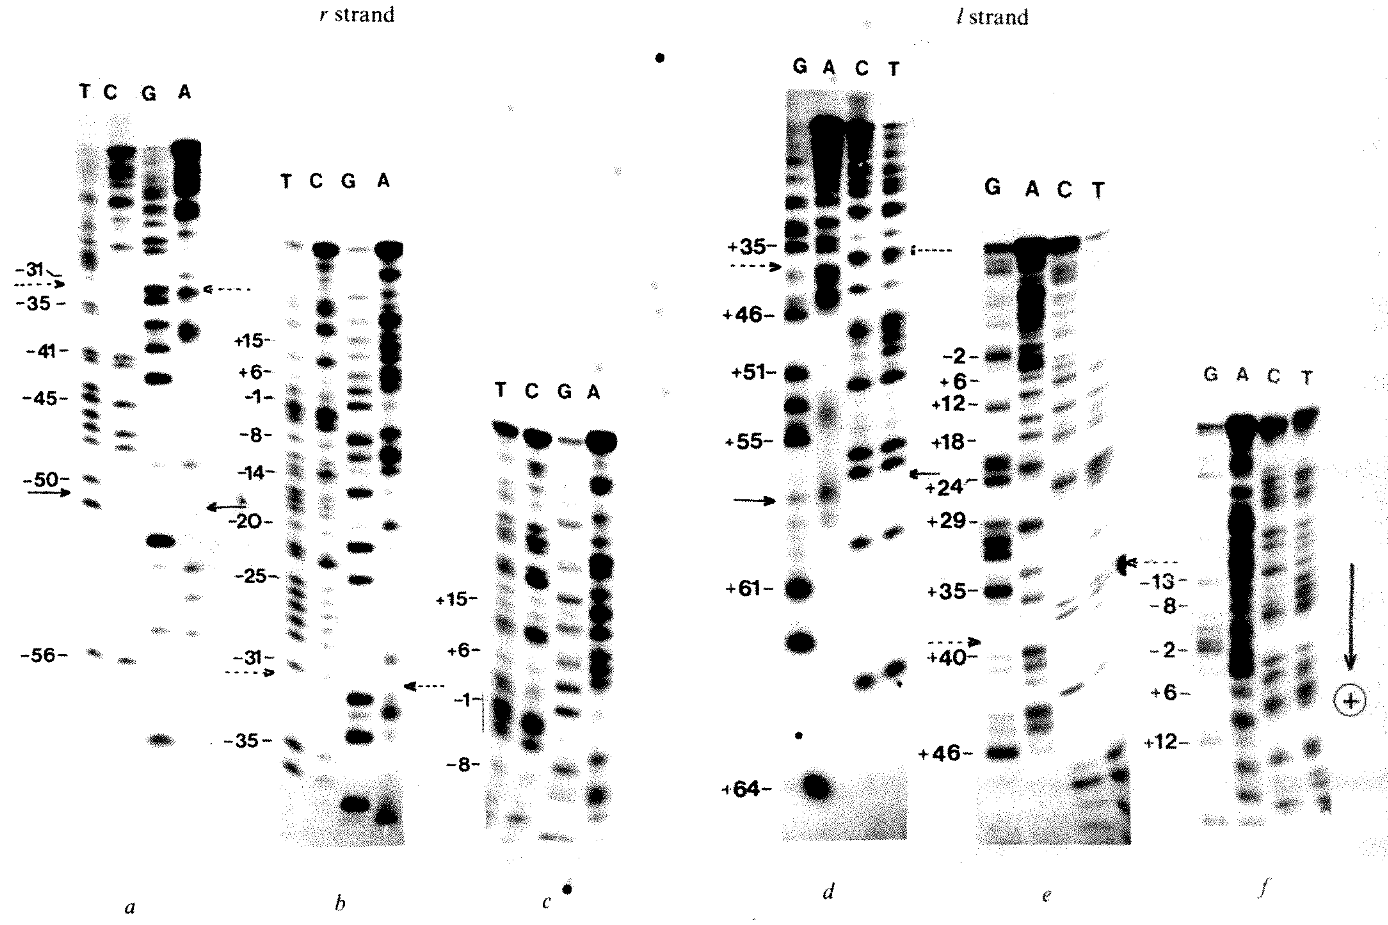

Fig. 3 Determination of the sequence of the *r* strand and the *l* strand of fragment *Hpa*II·F with the dimethylsulphate–hydrazine technique. 80 µg of sonicated calf thymus DNA were added to the separated strands, isolated as described in Fig. 2. After ethanol precipitation the material (about 1 × 10^5 Čerenkov counts) was divided into four equal parts. The two dimethylsulphate reactions (G and A specific; 30 °C and 37 °C respectively) were carried out in 500 µl of 50 mM sodium cacodylate, *p*H 8.0, 10 mM $MgCl_2$, 0.1 mM EDTA containing 1–2 µl of 10.7 M dimethylsulphate; the two hydrazine reactions were carried out at 37 °C in volumes of 50 µl (15 M hydrazine for the T-specific and 15 M hydrazine, 1 M NaCl for the C-specific reaction). The work-up of the reaction mixtures followed essentially the protocol of W. Gilbert and A. Maxam (personal communication and ref. 17). Incubation times were 60 min for the experiments shown in (*a*) and (*d*), 45 min for (*b*) and (*e*) and 30 min for (*c*) and (*f*). The cleavage products were finally fractionated on a 20% denaturating polyacrylamide slab gel (20 cm × 40 cm × 0.2 cm) containing TBE-buffer and 7 M urea. Electrophoresis was performed at room temperature applying 450 V for 17 h (*a*) and (*d*), 500 V for 42 h (*b*), 600 V for 21 h (*e*) and 600 V for 61 h (*c*) and (*f*). For the experiments shown in (*a*) and (*d*), a prerun was made at 600 V for 4 h. After electrophoresis the wet gels were covered with polyethylene wrap and exposed to X-ray film at −20 °C for 6–10 d. The numbers besides the autoradiograms refer to the corresponding positions of the *Hpa*II·F sequences shown in Fig. 4. The solid and dashed arrows give the position of the brompohenol blue and of the xylene cyanol FF markers, respectively. The columns labelled, T, C, G and A show the products of the T-, C-, G- and A-specific reactions, respectively. The heavy bands on top of each column represent unreacted starting material.

('A-specific' reaction). Limited reaction with hydrazine and no salt leads to a final product pattern with equal intensities for every T and C position ('T-specific' reaction), while the addition of 1 M sodium chloride to the hydrazine reaction mixture results in dark bands for the C positions and in light bands for the T positions ('C-specific' reaction).

Figure 3 shows the product patterns obtained by this technique for the separated *r* and *l* strands of the DNA fragment *Hpa*II·F. Three autoradiograms taken from three different electrophoresis gels are shown for each strand. They add up to more than 70 nucleotides for each strand. The final sequence as derived from both complementary strands is given in Fig. 4.

The following comments about the autoradiograms should be noted.

(1) The enzyme *Hpa*II recognises the double-stranded equivalent of the sequence 5′-CCGG-3′ cutting after the first C to produce restriction fragments starting with CGG at the 5′ ends[13]. However, the very first nucleotides of the chains could not be resolved, and the lowermost bands clearly visible in Fig. 3*a* and *d* indeed correspond to the third nucleotides from the 5′ ends (nucleotide numbers −57 and +64, respectively). This can be deduced from the bromphenol blue marker, which indicates the position of fragments 10 nucleotides long and by comparing the sequence derived from the *l* strand with the overlapping portion of the DNA sequence reported in ref. 15.

(2) There are two positions in the autoradiograms shown, where the G-specific reaction gives dubious results: the G at position +11 (*l* strand) and the A at position −10 (*r* strand). In the first case, the G-specific reaction gives a rather weak band compared with the G band corresponding to position +12, while in the second case a rather strong band appears at an A-position (but in the G-specific reaction). These irregularities have proved to be reproducible in several experiments. The ambiguities could be resolved, however, by looking at the corresponding positions of the complementary strand sequence. Further independent proof for the GG sequence in position +11/+12 (*r* strand) comes from the fact that the synthetic decanucleotide d(T-G-G-A-T-C-T-A-T-C) containing this GG doublet can act as primer in this region (position +13 to +4) (D. Ghosal, unpublished work from this laboratory).

(3) The CTCCT sequence at positions −5 to −1 in the *r* strand is not clearly resolved, but by inspecting the corresponding product pattern derived from the *l* strand, the sequence AGGAG (−1 to −5) can clearly be seen.

(4) Occasionally 'ghost' bands can be detected; these are due to small cross contaminations by the complementary strand. They can easily be assigned to the complementary strand, if the products of the four reactions of both strands are fractionated side by side on the same gel. As an example, the three ghost bands at positions −48, −46, and −44 in the G-specific reaction of the *r* strand (Fig. 3*a*) represent the G positions +55, +53, and +51 of the contaminating *l* strand (Fig. 3*d*).

Sequence features of the *oop* DNA and of the p_O promoter region

The sequence of the fragment *Hpa*II·F as resulting from the autoradiograms shown in Fig. 3 is presented in Fig. 4 in two halves; the upper part shows the section (*oop* DNA) transcribed into *oop* RNA; the lower part represents the section not being transcribed including the p_O promoter region. For comparison, the sequence of the λ promoters p_R and p_L as taken from ref. 18 are included in this figure. The segment including positions +53 to +66 is identical to the corresponding part of a sequence reported in ref. 15. (From this overlap the position of fragment *Hpa*II·F on the physical map of λ, as shown in Fig. 1, could be deduced.) From the DNA sequence determined we predict a sequence for the *oop* RNA (written as the top line in Fig. 4), which deviates from the reported sequence[7] at three positions (underlined in Fig. 4) as follows.

(1) According to the present data the triplet GCC has to be inserted at the positions 60 to 62, which is in accordance with this part of the sequence given in ref. 15. (2) At position 46 a single C residue replaces an octanucleotide GCCGCCUU of the reported sequence (positions 46 to 53 of ref. 7). (3) Finally there are two C residues proximal to the AU dinucleotide at positions 33–34, and only one C residue distal to it, instead of the reverse.

Fig. 4 Comparison of the sequence of the promoter p_O with the promoters p_R and p_L of phage λ. The sequences of the p_R and p_L promoters were taken from refs 18 and 32. The sequence predicted for the *oop* RNA is written on top of the transcribed section of the *Hpa*II F fragment; at the positions underlined the shown sequence deviates from the RNA sequence reported in ref. 7, as discussed in the text. The start points of transcription of the genes adjacent to p_L and p_R are indicated by horizontal arrows at the left ends. The boxes at left show the RNA polymerase binding sequences[21] of the three promoter regions. The solid and dashed boxes further to the right point out sequences of total or partial (AT versus GC) homology between the three promoter regions. The presumed repressor binding sites in the p_R and p_L promoter regions[18,32] are indicated by solid brackets, a similar sequence in the p_O promoter region by dashed brackets. The positions of the *Hind*II sites in p_R and p_L are also shown. The p_R promoter is given as the inverse of its usual orientation in λ DNA.

This latter change is in agreement with the absence of an *Eco*RII cut from the *oop* DNA region (DNA pregrown under *mec*$^-$ conditions[19]; unpublished observation from this laboratory). The CCUGG of the original sequence, which is the RNA analogue to one of the two recognition sequences of the *Eco*RII restriction enzyme[20], is now replaced by the sequence UCUGG in positions 34 to 38 (Fig. 4). As a consequence of the revisions given here, the entire sequence of the *oop* RNA is now predicted to consist of 77 rather than of 81 nucleotides.

In the promoter model put forward by D. Pribnow[21], a promoter comprises three essential elements covering about 40 base pairs of DNA: a 'recognition' sequence, a 'binding' sequence, and an RNA initiation point. Five or six base pairs separate the binding sequence from the initiation point and a distance of about 20 base pairs is postulated between the binding and the recognition sequences. All the nine promoters the sequences of which have been published (see refs 21 and 22) show strong homology in a seven base pairs region which is believed to define the binding sequence[21,23]. The p_O promoter region presented in this paper fully confirms this rule as indicated by the boxed sequence of Fig. 4, six base pairs ahead of the start point of transcription. While the binding sequence has now been well accepted, there is still uncertainty about the basic structure of the RNA polymerase recognition site. Comparison of the λp_R and λp_L promoters with a promoter for *E. coli* RNA polymerase in SV40 DNA (ref. 18) and of the G2 and G3 promoters of phage fd DNA with the same SV40 promoter[22] revealed a five base-pair homology between these promoter sequences in the regions of the presumed recognition sites. The sequence of the p_O promoter region presented in Fig. 4 substantiates these findings. If one aligns these promoter sequences relative to their common binding sequences (and not to their RNA initiation points), a homologous hexanucleotide sequence emerges:

λp_{O}	5′ AGTTGA 3′
λp_{R}	TGTTGA
λp_{L}	TGTTGA
SV40	TGTTGT
fdG2	TGATGC
fdG3	CGTTGT

This sequence is placed always 20–25 nucleotide pairs ahead of the binding sequence (19–24 in the case of the fdG3 promoter). As has already been noticed[21,22] the *lac* and the *tyrosine tRNA* promoter sequences do not fit into this group. Obviously, more sequence data are necessary in order to identify possible additional groups of basic recognition sequences. (Due to a different adjacent nucleotide (Fig. 4) the p_{O} promoter DNA is just missing to also contain a *Hin*dII site (GTPyPuAC) as do the promoters λp_{R} and λp_{L} in this area.)

The λ promoters p_{R} and p_{L} overlap with the serial operator sequences in O_{R} and O_{L} (refs 18 and 32). Whereas the structural features of $O_{\mathrm{R}}1$ (or $O_{\mathrm{L}}1$) seem to be absent from the p_{O} promoter sequence, an operator-like sequence can be detected in the p_{O} promoter region, which is in exact register with the $O_{\mathrm{R}}2$ and $O_{\mathrm{L}}2$ operators (indicated by dashed brackets in Fig. 4). This sequence could be expected to act as a repressor binding site, but no reduction of the *oop* RNA transcription rate upon the presence of repressor has been observed *in vivo*[8]. In addition, no binding other than to the O_{R} and O_{L} fragments has been observed with λ*c*I repressor and *Hpa*II digestion mixtures of λDNA (ref. 24) and λ*dv*h93 DNA *in vitro* (unpublished observation from this laboratory). Since binding sites for the *cro* gene product in O_{L} and O_{R} apparently overlap with *c*I repressor binding sites, an alternative explanation for the operator-like sequence in the p_{O} promoter region would be to function as an interaction site for the *cro* protein. This possibility remains to be tested directly, although several mutations of phage λ have been mapped in this part of the *ori* region which show an increased sensitivity against *cro* (ref. 25). To identify other possible significant sequence structures, work is in progress to extend the known part of the p_{O} promoter region.

We thank Drs W. Gilbert and A. Maxam for kindly providing us with a detailed protocol on their methods for strand separation and for degradation of labelled polynucleotides with dimethylsulphate and hydrazine before publication. We thank Miss S. Baars and Mrs E. Schiefermayr for technical assistance. Helpful criticism of the manuscript by Dr R. Hausmann is gratefully acknowledged. This work was supported by a Promotions-stipendium from the Studienstiftung des deutschen Volkes to G.S. and by grants from the Deutsche Forschungsgemeinschaft to G.H. and H.K.

X-ray flare in 3U 0833−45 the Vela pulsar

DURING an extended observation with the Ariel V Sky Survey Instrument (SSI) a flare has been detected from the X-ray source 3U 0833−45, generally associated with the Vela pulsar. Details of the SSI, which covers the energy range 2.4–18 keV, are given elsewhere[1]. The flare occurred during the first part of 24 July 1976, reaching a peak intensity at ~0300UT of 11.9 ± 1.7 counts s^{-1}, a factor of three above its normal (Ariel V) level, and lasting ~0.5 d. Figure 1 shows the light curve of the event, and it is interesting to note a possible precursor to the main flare, occurring approximately 2 d earlier. No similar event or measurable variability has been seen in observations of 3U 0833−45 with the SSI over the previous 20 months. A typical run of data from August 1975 with 3U 0833−45 in its normal (quiescent) state is shown in Fig. 2. These lower flux values have been summed in 0.7 d bins for clarity in the figure.

3U 0833−45 is believed to be associated with the pulsar PSR 0833−45 (ref. 2) itself probably a remanent of the Vela SN explosion[3]. Pulsed emission at both hard[4] and soft[5] X-ray energies have been claimed for this pulsar, although, as yet, efforts to confirm these results have proved unsuccessful[6–8]. It appears that the earlier results were incorrect or that the pulsed component is highly variable.

The chance of an unknown field source appearing briefly in the $0.7° \times 10°$ (FWHM) collimator of the SSI and coincident with the Vela pulsar in the scanning direction (offset $= 0.1° \pm 0.2°$) cannot entirely be ruled out. However, consideration of the frequency of such transient events found by Ariel V makes this very unlikely. Accepting, then, that the observed flare is indeed from the pulsar and taking a distance of 460 pc[10] the total emitted energy (2–10 keV), assuming the spectral shape of Kellogg *et al.*[2], of the main and precursor flares is $2.9 \pm 0.3 \times 10^{38}$ erg and $1.2 \pm 0.3 \times 10^{38}$ erg respectively.

Mapping of the Vela region with Ariel V (A. Smith, unpublished) has confirmed the result first obtained from an analysis

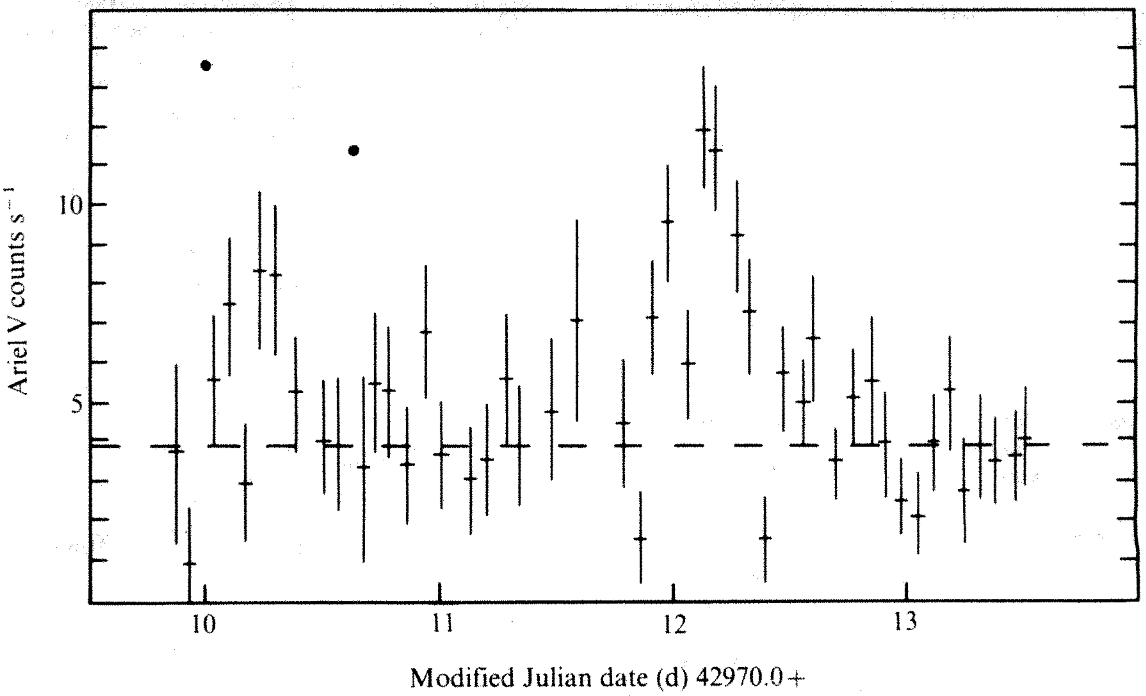

Fig. 1 Single orbit observations of 3U0833−45 during July 22–25 1976. Error bars are $\pm 1\sigma$. The broken horizontal line represents the normal flux for this source.

of Copernicus X-ray data by Silk[11], that the emission region around the Vela pulsar is extended. This extension is consistent with the normally steady X-ray emission of 3U 0833−45 and it is probable that the variable component now associated with the pulsar is generally undetectable and, correspondingly, that the variability of this point source component is much greater than a factor of three. This conclusion offers the possibility that the large pulsed component found by Harnden and Gorenstein[4] was indeed correct and occurred during a period of enhanced emission. The likelihood of a short rocket observation coinciding with such a flare can be estimated from the previous SSI data, some 600 orbits of which spread over 20 months detected no similar flares. The estimated probability of a flare coinciding with one of six reported observations is < 10%.

The 0.5 d timescale of the present X-ray flare may give a clue to its origin. Unfortunately no timing data was available during the observations and therefore it is not known whether the X rays were pulsed at the 89 ms period of PSR 0833−45. However, the absence of a concurrent change in the radio frequency ($\Delta\omega < 5\times10^{-10}\omega$, Manchester, personal communication) argues against the pulsar being the source of the flare. Equally, the short time scale rules out a major change in the X-ray emission of the extended nebular source (diameter of 30 arc min $\simeq$ 12 light years at 460 pc). The most probable source of the X-ray flare appears to be a redistribution of the magnetic field and particle flux in the magnetosphere of the pulsar. Scargle and Pacini[12] have discussed this possibility for the Crab Nebula to explain the occurrence of pulsar 'spin-ups' and 'spin-downs' and the considerably greater energy associated with the concurrent wisp activity.

The energy stored in the magnetosphere of PSR 0833−45 may be of the order of the magnetic energy of the neutron star: $\sim B_0^2a^3$ (B_0 is the surface field and a the stellar radius). For $B_0 \sim 2\times10^{12}$ gauss (ref. 13) and $a \sim 10^6$ cm, the stored energy $\sim 4\times10^{42}$ erg. Beyond this region of magnetic trapping current models, for example Rees and Gunn[14], envisage a relativistic wind flowing out radially to a shock boundary, where the outflow pressue is balanced by the gas pressure of the surrounding nebula. A release of energy from the pulsar magnetosphere, producing a temporary enhancement in the wind, would then give rise to enhanced synchrotron emission on striking the shock boundary. Although it is difficult to estimate the radius of this shock in Vela (no wisps seen, pressure in outer nebula uncertain), scaling from the Crab Nebula

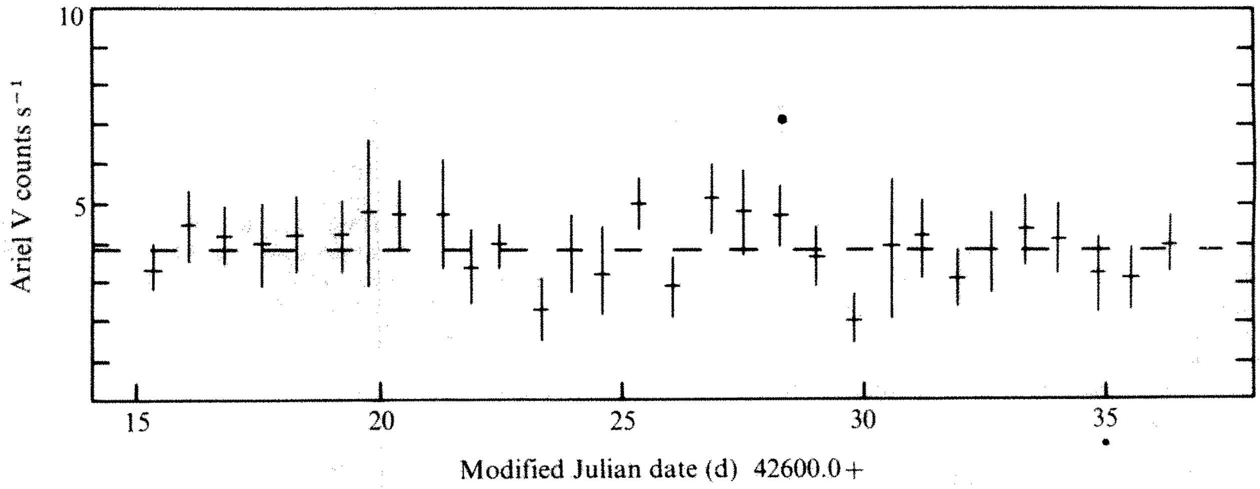

Fig. 2 0.7 d summed observations of 3U0833−45 during August 1975.

according to the ratio of mean pulsar losses (60:1), suggests $R_s \sim 5 \times 10^{16}$ cm for Vela. The observed flare timescale of ~0.5 d (10^{15} light s) may be satisfied if only part of the shock boundary is affected or, perhaps more likely, the beaming of the synchrotron X rays restricts the observed emission to that arising from the fraction of the shock surface beaming radiation in our direction.

We thank Drs R. Blandford and J. Pringle and Professor M. J. Rees for discussions. Ariel V is a Science Research Council project and A. S. is also supported by an SRC research studentship.

The missing intercloud medium and spiral galaxies

IT is the purpose of this letter first to point out that several independent lines of evidence seem to indicate that the 'intercloud medium' does not exist in its usually quoted state with density $\gtrsim 0.1$ cm^{-3} and temperature $T \sim 10^4$ K. Rather, a hot, tenuous medium ($n \lesssim 10^{-2}$ cm^{-3}, $T \sim 10^6$ K) seems more consistent with observations in the neighbourhood of the Sun. That such might be the situation has been previously suggested (see refs 1 and 2). A mechanism for producing such a medium has been proposed by Cox and Smith[3]. Second, this letter points out several implications of such a "missing intercloud medium" on the large-scale structure of spiral galaxies.

The lines of evidence pointing to the preponderance in the solar vicinity (within 1 kpc) of an intercloud medium having $n \lesssim 10^{-2}$ cm^{-3} and $T \sim 10^6$ K (which we will call "Phase III" gas) are as follows: (1) Steigman, Strittmatter, and Williams[4], studying ultraviolet interstellar absorption lines, find no correlation between distance to the illuminating star and absorption line strengths for lines which arise from 'classical Phase II' ($n \gtrsim 0.1$, $T \sim 10^4$ K) intercloud gas. Instead, Phase II absorption line strengths are correlated with spectral type, indicating that circumstellar rather than interstellar Phase II gas is being observed. Column densities and ionisation states are shown to be consistent with circumstellar gas conditions one would predict from stellar wind theory.

(2) Ubiquitous interstellar O VI absorption is observed[2]. The absorption strength is apparently correlated with distance to the illuminating star, while the radial velocities of the star and interstellar line are uncorrelated. The O VI ion is expected to be present in the ultra-hot Phase III medium, but not in the 10^4 K Phase II medium.

(3) Very stringent upper limits ($n_{\mathrm{HI}} < 0.02$) exist on the neutral hydrogen density in the directions of two hot white dwarfs detected by the Apollo–Soyuz EUV experiment at wavelengths of 50–600 Å. (refs 5, 6). Detection of a third source identified with another hot white dwarf, by another rocket-borne EUV experiment[7], has recently placed a similar upper limit on n_{HI} in a third direction. In each of the three cases, the upper limits refer to averages over distances of about 75 pc. Even more dramatic, therefore, may be the non-detection by Copernicus of interstellar Lyman α absorption in the spectra of seven B stars located in the galactic plane at distances of up to several hundred parsec[8], particularly if we follow ref. 4 and attribute many or all of the detections of interstellar Lyman α absorption in spectra of other stars observed by Copernicus to circumstellar material. It is important to note that these low neutral hydrogen densities cannot be explained as being due to highly ionised Phase II gas, since this explanation would violate the upper limit on electron densities derived from pulsar dispersion observations[9] ($n_e < 3 \times 10^{-2}$). The low upper limits for both n_{HI} and n_e are of course consistent with the Phase III picture.

(4) When an expanding supernova remnant encounters a region of very low density, the remnant may disappear as a recognisable entity. If large fractions of the interstellar medium are in Phase III, this effect should cause a deficit of large radius supernova remnants. Jones[10] has analysed the observations of remnant sizes and concludes up to 80% (by volume) of the interstellar medium is Phase III.

(5) An interstellar medium primarily composed of Phase III gas will have a galactic scale height ~1 kpc. Therefore, both the temperature and distribution of the proposed Phase III interstellar medium are consistent with the soft X-ray background[11,12].

(6) It is also interesting to note that the "observed" mean density of the gas which is purported to be the Phase II intercloud medium is inconsistent with the amount of matter traversed by, and lifetime of, galactic disk cosmic rays.[13]

(7) New 21-cm observations of the interstellar medium in the direction of bright high-galactic-latitude continuum sources (J. M. Dickey, G. E. Salpeter, and Y. Terzian, personal communication) seem to provide no evidence for the existence of a pervasive Phase II medium, although the presence of such a medium has been inferred from older observations of the same type.[14] An 'intercloud' ($T_{\mathrm{sp}} > 500$ K) contribution to the emission and absorption profiles observed definitely exists, but appears to be correlated in velocity with the cloud ($T_{\mathrm{sp}} \sim 60$ K) contribution. Much of the 'intercloud' contribution also must come from warm gas of a few hundred degrees (J. M. Dickey, E. E. Salpete and Y. Terzian, personal communication). These observations are completely inconsistent with the strict pressure-equilibrium two-phase model, and in fact seem to provide no evidence for the existence of any interstellar material not associated with clouds.

If one assumes that the mechanism which produces the ultra-hot interstellar medium in the solar neighbourhood of our Galaxy is that proposed by Cox and Smith[3] (heating by shock waves from supernovae), then we can estimate the likelihood of also finding the Phase III medium in other spiral galaxies. Cox and Smith[3] define a porosity, q, which is related to the fraction of the interstellar medium occupied by tunnels of very hot Phase III material

$$q \propto R\, n_0^{-1.7}$$

where R is the supernova rate and n_0 is the mean interstellar gas density. We take relative values of R (for various spiral types) from Tammann,[15] and assume relative values of n_0 are given by the relative values (for the various spiral types) of the ratio of H I mass to total galactic mass.[16] We find that values of q in the Sa, Sb, and Sc galaxies are all within 20% of the local value in our Milky Way, that is

$$0.8 \leq \frac{q(\text{Sa, Sb, Sc})}{q(\text{Milky Way})} \leq 1.2$$

It therefore seems that a Phase III interstellar medium (with embedded cooler clouds and circumstellar shells) could be a general phenomenon in spiral galaxies. This has significant implications for theories of star formation in spiral arms that invoke the mechanism of a galaxy-wide, density-wave driven shock wave in the Phase II interstellar medium.

Large scale galactic shocks and corresponding filamentary spiral structure can form in the interstellar gas only if the gas is driven strongly enough to force the velocity component normal to a spiral arm, $w_\perp$, to oscillate about its unperturbed value $w_{\perp 0}$ and achieve transsonic values. Studies (see refs 17 and 18) which estimate the relative speed, $w_{\perp 0}$, of the density wave pattern and the interstellar medium suggest typical values $w_\perp \leq$ 25–50 km s^{-1}. Simultaneously the effective acoustic speed, a, is $\sim$7–12 km s^{-1} if the gaseous component is largely Phase II gas, and the formation of strong shocks in this situation is rather natural.[19]

On the other hand, if the intercloud medium is predominantly 'Phase III' gas, as it seems to be in the solar neighbourhood, the effective acoustic speed, a, is $\sim$100 km s^{-1}, and the formation of strong shocks is rather unlikely except in extreme circumstances of severe forcing. This implies that either the shock wave picture of star formation in spiral arms needs to be abandoned for galaxies with predominantly Phase III intercloud medium, or that density waves in such galaxies are strongly nonlinear. (Strom *et al.*[20] have studied two galaxies which have spiral patterns in the old population stars, but lack the usual hot, young stellar population spiral arm tracers. We suggest these may be two examples of galaxies which have high enough porosity to preclude the formation of shocks and consequent star formation.)

Galaxies with Phase III gas throughout both arm and interarm regions seem likely to be quite uncommon, however. This is because the Phase III gas is formed primarily in the supernova-rich spiral arms and the cooling time for this gas is shorter than the time it takes the gas to travel between spiral arms (B. Smith, personal communication). It seems more probable, therefore, that Phase III gas dominates the intercloud medium in most spirals only near spiral arms, where most supernovae occur. The Phase III gas then cools to a Phase II medium in the interarm region. This newly cooled medium could then experience a shock on encountering the next density wave enhancement (indeed, the skewed character of spiral arm 21-cm profiles seems to imply shocks)[21]. The shock wave would produce more young stars which would result in supernovae which would in turn re-heat the interstellar medium to a Phase III temperature, thus completing the cycle. Such a situation would significantly affect the pressure and density of gas in the plane as a function of azimuthal angle, perhaps leading to an explanation of the observed lack of strong compressional effects in the spiral arm non-thermal continuum emission[22]. Of course for this type of picture to be consistent with all the observations in our Galaxy the Sun must lie near or within an active region of star formation and supernovae, where Phase III gas can be generated, such as a major spiral arm or a secondary feature or spur.

Limit on the frequency of intergalactic supernovae

WE shall turn the simple observation that "there are no intergalactic supernovae" into a quantitative statement for the Coma cluster of galaxies. In this cluster, where at least 30% of the total luminosity lies outside the regions normally associated with individual galaxies[1–3], the absence of intergalactic supernovae can be used to derive restrictions on the nature of the luminous intergalactic material, be it a diffuse collection of stars, a background of low surface brightness dwarf galaxies, or some other form of luminous matter.

Relevant data on the supernovae within 3° of the Coma cluster centre are collected in Table 1. Most of the data came from the list of Sargent *et al.*[4], except the data on SN 1976 (*IAU Circular* no. 2921, 1976; the radial velocity from ref. 5), and the type of the parent galaxy of SN 1962i (ref. 6).

Two supernovae listed in Table 1 fall well within the Holmberg radius of the foreground galaxy NGC 4725 (SNe 1940b, and 1969h). As a luminosity class I Sb-galaxy[7] this object is expected to be a good supernova producer. In addition, it is very unlikely that the coincidence in position is a product of chance and that these supernovae belong to the Coma cluster background: within 3° from the cluster centre there are only five foreground galaxies brighter than m_{pg} = 15.0 mag (ref. 8); their combined Holmberg area covers $\approx 3\times10^{-3}$ of the total area. Even when allowance is made for fainter, unidentified foreground galaxies, the probability of a Coma cluster supernova falling by chance within the Holmberg radius of a foreground galaxy is smaller than 10^{-2}. One supernova of Table 1 (SN 1968h) belongs to an anonymous galaxy, the high redshift of which lies well outside the typical velocity interval of Coma cluster galaxies[9] and identifies this galaxy as a background-object. The supernova is most probably physically associated with this galaxy: its central distance is only 0.03 Holmberg radii. We will exclude these foreground and background objects from our discussion.

No radial velocities are available for the parent galaxies of SNe 1962i and 1963m. We adopt these galaxies as Coma cluster members because the probability of cluster membership is high for any galaxy in the field considered, and because the morphological appearance of the galaxies agrees well with the hypothesis of cluster membership. The parent galaxy of SN 1962i is quite faint: although it seems somewhat brighter than m_{pg} = 19 mag assigned by Zwicky *et al.*[6], it could be a distant background galaxy. However, the fact that the SN 1962i was brighter at discovery ($16^{m}.5$) than its parent identifies the latter as a dwarf galaxy[10], and hence as a very probable Coma cluster member. Our sample contains ten Coma cluster supernovae; of these, five have been assigned types: four as type I and one as peculiar[4].

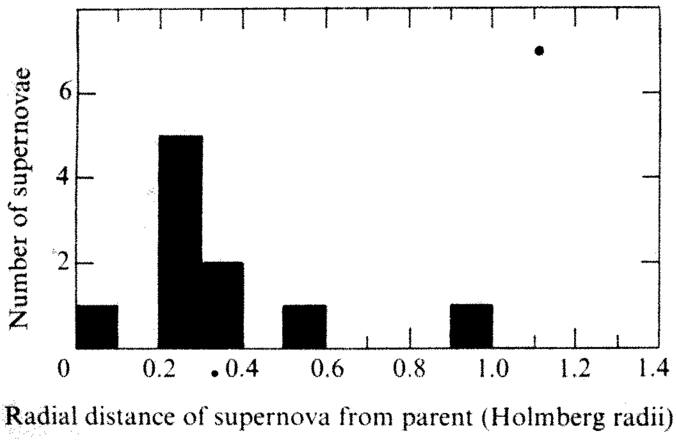
†Heliocentric radial velocity.
‡Apparent magnitude of parent.
§Distances of supernova from centre of parent (east–west and north–south).
∥Radial distance of supernova from parent in units of the Holmberg radius, derived as described in text.

The radial distances given in Table 1, column 11, were calculated by assuming that the outer isophote of each galaxy is an ellipse with the major and minor axis given by the Uppsala diameters[11]. Galaxies not appearing in the Uppsala list were measured independently, and these measures were converted to the Uppsala scale. Using the Uppsala diameters and position angles and the supernova distances of Table 1, we determined the ratio of the supernova distance to the distance of the Uppsala isophote at the same position angle. These radial distances were converted to distances in units of Holmberg radii[12] using a scaling factor determined from galaxies common to both lists. Figure 1 shows a histogram of these radial distances.

To estimate the supernova rates per unit luminosity in the Coma cluster, the following quantities are needed: the luminosity in galaxies within our 3° radius, the effective number of search years, and the relative luminosity in spiral and elliptical galaxies. For the luminosity within a 3° radius, we take the value $L = 9.6\times10^{12}\,L_{\odot}$ derived from the data of Thuan and Kormendy[2] using the model proposed by King[13] to extrapolate to 3°. ($H_0 = 55$ km s^{-1} Mpc^{-1} is assumed throughout.) This value agrees within a factor of two with the values found by other observers[14,15]. Barbon[16] estimates the efficiency of the Palomar supernova search to be 90% between 1957 and 1967. Our list contains six supernovae discovered during this time, and hence one could conservatively estimate that our sample of ten Coma supernovae corresponds to 15 effective search years. This number is consistent with the fact that the Coma field was surveyed at Palomar alone during 96 different months in the years 1958–1971 (ref. 4). However, the uncertainties in this estimate are difficult to evaluate, and we consider this only as a reasonable indication of the effective search time. The ratio of luminosity in ellipticals to that in spirals can be estimated from the data for the brighter cluster members provided by Rood *et al.*[14], and we will take $L(\mathrm{E/SO}):L(\mathrm{Spirals}) = 6:1$.

Fig. 1 Histogram of radial distribution of supernova in the Coma cluster galaxies.



The above data imply the following supernovae rates for the eight supernovae in E/SO galaxies and for the two supernovae in spirals

$$\nu_c\,(\mathrm{E/SO}) = 6\pm2\ \mathrm{SNU}$$
$$\nu_c\,(\mathrm{Spirals}) = 8\pm5\ \mathrm{SNU}$$

where the units of SNU (supernova units) are SNe (100 yr)$^{-1}$ $(10^{12}\,L_{\odot})^{-1}$. These numbers are dependent on the assignment of types to the parent galaxies. If we had adopted the types from Maza and van den Bergh[7], the frequency in E/SO galaxies would have been decreased by about a factor of two and that in spirals increased by roughly the same factor. For comparison, the rates in nearby galaxies given by Tammann[17] are

$$\nu_{NB}\,(\mathrm{E/SO}) = 25\pm10\ \mathrm{SNU}$$
$$\nu_{NB}\,(\mathrm{Sa}) \approx 20\ \mathrm{SNU}$$
$$\nu_{NB}\,(\mathrm{Sc\text{-}Irr}) = 140\pm20\ \mathrm{SNU}$$

The rates for the Coma cluster galaxies may be less than for the nearby sample. This may not be statistically significant, but if it were, it might have been anticipated in view of the fact that the searches tend to discriminate against supernovae in the centres of more distant galaxies[4]. If we use the results of Sargent *et al.* on supernova frequencies as a function of the apparent magnitude of the parent galaxy as the basis for an extrapolation from Tammann's nearby galaxy sample to the distance of the Coma cluster, we would expect to find a still lower supernova rate (by a factor ~ 2) in the Coma cluster than in fact we do. Thus we conclude that the region of the Coma cluster has been quite carefully surveyed and that the galaxies are producing supernovae at about the same rate as the nearby galaxies.

An upper limit to the intergalactic supernova rate can be derived from the value for the intergalactic luminosity. We again use the data of Thuan and Kormendy[2] and the model of King[13] to derive the value $L = 5.0\times10^{12}\,L_{\odot}$ as the luminosity outside the Holmberg radii of the galaxies. This estimate agrees with that of de Vaucouleurs[1]. Since none of the ten supernovae in our sample have occurred outside the Holmberg radius of the parent, we derive a limit on the intergalactic supernova rate by assuming one intergalactic supernova

$$\nu_{IG} < 1 \text{ SNU}$$

This rate is more than six times less than our observed rate in Coma cluster E/SO galaxies and more than ten times less than the rate in nearby E/SO galaxies.

An independent limit on the relative efficiency of the intergalactic material for producing supernovae can be derived by the following argument. We observe no supernovae outside the Holmberg radius in ten examples. This would occur with 50% probability if only 6.7% of the supernova producing matter were outside the Holmberg radius. In fact, 34% of the total luminosity is exterior to the Holmberg radius and, hence, this intergalactic material is at least five times less efficient in producing supernovae than the material in galaxies.

Our entire discussion has assumed that the intergalactic region has been as carefully surveyed as the regions around the individual galaxies themselves. For the Coma cluster, we believe that this may be true since the cluster is rather compact, and the empty regions between galaxies are relatively small so that an observer would not be likely to miss supernovae even at large distances from the galaxies. As already mentioned, the searches tend to discriminate increasingly against central supernovae in more distant galaxies, and this effect should tend to increase the relative frequency of outlying supernovae. On the other hand, there is no quantitative way of estimating the search efficiencies in the intergalactic regions, so that our conclusions on the intergalactic supernovae rates could be taken, at worst, as limits on the relative survey efficiency. Clearly, we do not support this view, but cannot be quantitative and must rely on what we know and hear about how the searches are conducted. At least in the case of the Palomar search, the plates have been uniformly blinked over the entire region (C. T. Kowal, personal communication).

With the above caveat, we conclude that the intergalactic medium is deficient in supernova progenitors by a factor of $\geqslant 5$. This holds independent of the nature of the luminous material, be it the effect of overlapping haloes of E/SO galaxies, the light of undetected dwarf galaxies, or of any other origin.

We thank C. T. Kowal for helpful information on the Palomar supernova searches. One of us (G.A.T.) acknowledges partial financial support from the Swiss National Science Foundation.

Demonstration of upper and lower Newtonian fluid behaviour in a pseudoplastic fluid

THE most common type of non-Newtonian fluid is the pseudoplastic fluid. The pseudoplastic fluid is characterised by a constant viscosity at very low shear rates, a viscosity which decreases with shear rate at intermediate shear rates, and an apparently constant viscosity at very high shear rates. That is

$$\lim_{\dot\gamma\to 0}\,[\tau/\dot\gamma] = \eta_0 \text{ (zero shear viscosity)} \qquad (1)$$

and

$$\lim\,[\tau/\dot\gamma] = \eta_\infty \text{ (infinite shear viscosity)} \qquad (2)$$

The apparent viscosity defined by

$$\eta = \tau/\dot\gamma \qquad (3)$$

then decreases with shear rate from η_0 to η_∞ and the pseudoplastic fluid exhibits a lower and upper region of Newtonian behaviour. Examples which illustrate the zero shear viscosity and the decreasing viscosity region for pseudoplastic fluids are very common and include almost all polymer melts and solutions. η_∞ is generally not well defined. Often the data available only approach the high shear rate limit and η_∞ is either determined by extrapolation or is set equal to zero which is a suggested theoretical value. Data which illustrate the three regions of pseudoplastic behaviour are rare and indeed are not quoted in the standard reference texts on rheology. The purpose of this communication is to present such data for a polymer solution and to compare the results to the models which are available for pseudoplastic fluids.

Expressions of varying complexity have been proposed to model pseudoplastic behaviour. The Meter model[1] contains η_0, η_∞ and two other parameters, τ_m and α.

$$\eta = \eta_\infty + \frac{\eta_0 - \eta_\infty}{1 + (\tau/\tau_m)^{\alpha-1}} \qquad (4)$$

τ_m is the shear stress at which the viscosity η has dropped to $\frac{1}{2}(\eta_0 + \eta_\infty)$ and hence is another measurable quantity. α is a measure of the rate at which η is reduced from η_0 to η_∞ and can be determined from the slope of a plot of $(\eta_0 - \eta)/(\eta - \eta_\infty)$ against τ on log–log coordinates, providing both η_0 and η_∞ are known. If $\eta_\infty \ll \eta_0$ then $\tau_m = \tau_{\frac{1}{2}}$, the shear stress at which the viscosity has dropped to $\frac{1}{2}\eta_0$, and the Meter model reduces to the Ellis model[2].

$$\eta = \frac{\eta_0}{1 + (\tau/\tau_{\frac{1}{2}})^{\alpha-1}} \qquad (5)$$

which in turn shows power-law behaviour at high shear stresses

$$\eta = K\tau^{1-\alpha} = \eta_0(\tau_{\frac{1}{2}})^{\alpha-1}\tau^{1-\alpha} \qquad (6)$$

Three instruments, a Brookfield viscometer, a Weissenberg rheogoniometer, and a gas-driven capillary rheometer were used to make shear stress–shear rate measurements over a large enough shear rate range to illustrate upper and lower Newtonian behaviour. A 0.4% weight polyacrylamide solution was used. The Brookfield viscometer with a cylindrical spindle of length 6.36×10^{-2} m and diameter of 1.87×10^{-2} m was used to measure the shear stress as a function of shear rate at low shear rates. Relative to the diameter of the spindle, the fluid medium in which the spindle was immersed was infinite in size. End

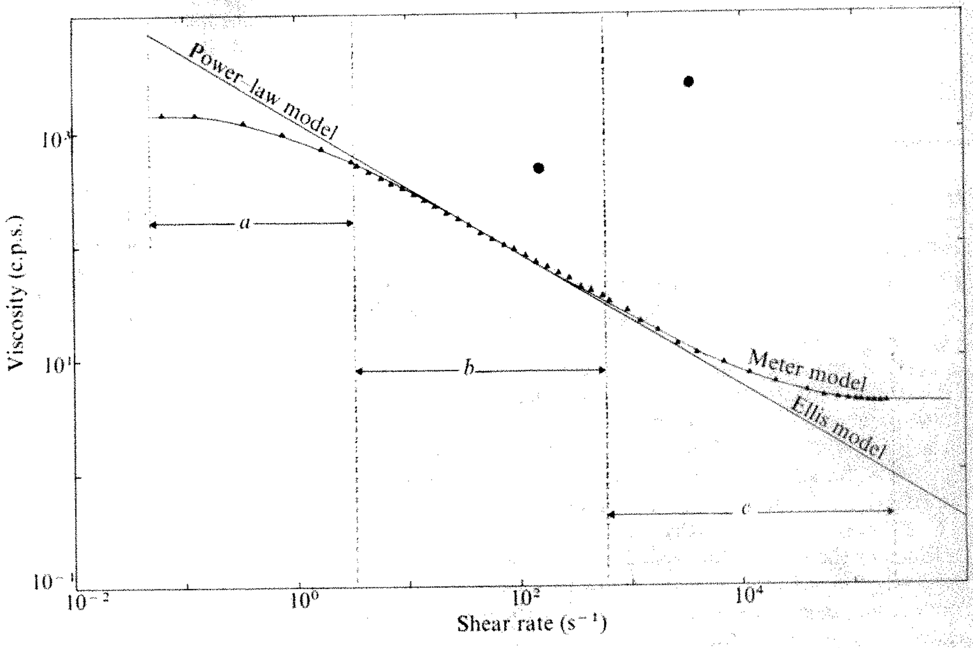

Fig. 1 Illustration of upper and lower Newtonian behaviour for a 0.4% polyacrylamide solution. *a*, Brookfield viscometer; *b*, cone and plate viscometer; *c*, capillary viscometer.

corrections were less than 10%. For this condition the shear stress and the shear rate on the surface of the spindle are given by ref. 5.

$$\tau_b = \frac{T}{2\pi R_b{}^2 L} \tag{7}$$

$$\dot{\gamma}_b = \frac{4\pi N}{n''} \tag{8}$$

where T = measured torque; R_b = radius of spindle; L = length of spindle; N = rate of revolution of the spindle (r.p.s.); n'' = slope of a log–log plot of τ against N for each value of τ.

A 2°1′26″ cone was used with a 0.075 m diameter plate in the Weissenberg rheogoniometer. For the small cone angle employed the shear stress and hence the shear rate do not vary in the gap between the cone and plate and the shear stress and shear rate are related to the torque exerted on the plate and the rate of rotation of the cone by[6]

$$\tau = \frac{3T}{2\pi R^3} \tag{9}$$

and

$$\dot{\gamma} = \Omega/\alpha \tag{10}$$

where R = radius of the platens; Ω = angular velocity of the cone; α = cone angle.

A gas-driven capillary rheometer was used for the high shear rate region. The tube internal diameter was 5.29×10^{-4} m and its length was 0.3789 m. Exit and entry pressure losses are negligible for such a high L/D capillary tube and the wall shear stress and wall shear rate are defined in terms of the measured pressure drop (Δp) and volumetric flow rate by[5,6]

$$\tau_w = \frac{R\Delta p}{2L} \tag{11}$$

$$\dot{\gamma}_w = \frac{3n+1}{4n}\left(\frac{4Q}{\pi R^3}\right) \tag{12}$$

where n is the slope of the log–log plot of τ_w against $4Q/\pi R^3$ at each value of $4Q/\pi R^3$.

Equations (7), (8), (9) and (10) were then used to reduce the torque as a function of angular velocity data, while equations (11) and (12) were used to express the pressure drop flow rate data obtained with the capillary rheometer in terms of the wall shear stress and wall shear rate. The results obtained with the three instruments are shown in Fig. 1 where the apparent viscosity defined by equation (3) is plotted against the shear rate. The polyacrylamide solution showed no appreciable shear degradation at the high shear rates employed in the capillary rheometer.

The results in Fig. 1 cover almost six decades of shear rate and the reproducibility between the various instruments is excellent. Upper and lower Newtonian behaviour is clearly illustrated with η_0 = 1425 cP and η_∞ = 4.0 cP. Also shown on Fig. 1 are the Meter, Ellis, and power-law model fits of the experimental data with τ_m = 1.215 N m^{-2}, α = 2.43 and $\tau_{\frac{1}{2}}$ = 1.211 N m^{-2}. Notice that the Meter model is an excellent representation of the data over the entire shear rate range, the Ellis model is inadequate for shear rates in excess of 250 s^{-1} and that the power-law model is strictly valid only for 25 s^{-1} $\leqslant \dot{\gamma} \leqslant$ 250 s^{-1}. The results also clearly illustrate the importance of measuring the flow properties of a pseudoplastic fluid in the range of shear rates for which the data is to be employed and further illustrate the importance of choosing the appropriate instrument and flow geometry for making these measurements. Clearly the measurement of the flow properties of a pseudoplastic fluid or for that matter any non-Newtonian fluid in a shear rate range other than that where the data is employed is a futile exercise.

I am grateful to the Australian Research Grants Commission for supporting the research in rheology conducted in the Department of Chemical Engineering at Monash University and to Mr R. Binnington, a technical assistant supported by this research grant.

Exact modelling of cubic lattice permittivity and conductivity

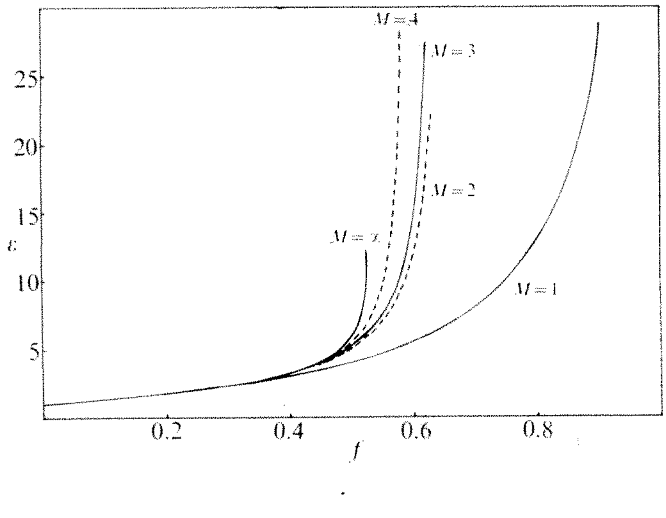
A PROBLEM of practical importance in a wide variety of situations is that of calculating the permittivity (or equivalently, the conductivity) of simple cubic arrays of spheres embedded in another material. Applications occur in, for example, the analysis of optical properties of inhomogeneous films[1], dielectric dispersion in mixtures[2], the behaviour of artificial dielectrics[3], the study of lunar soil samples[4] and in vision research[5]. Although the problem is an old one, and has attracted the attention of some of the great names of physics (for example, J. C. Maxwell[6] and Lord Rayleigh[7]) it seems that a completely satisfactory theory has not existed until the present time. This is shown by the fact that in the most critical case, that of perfectly conducting spheres, none of the existing theories give the expected divergence at the critical volume fraction ($f_c = \pi/6$) at which the spheres touch. We have extended Lord Rayleigh's treatment and present a theory which gives the correct behaviour for all volume fractions.

The first order (dipole) solution to the problem is known as the Lorentz–Lorenz equation or the Maxwell Garnett equation

$$\varepsilon = 1 - \frac{3f}{[(2+\varepsilon_1)/(1-\varepsilon_1)]+f} \tag{1}$$

where ε, ε_1 are, respectively, the permittivities of the resultant medium and of the spherical particles (both measured relative to the permittivity of the matrix); f is the volume fraction of the particles. The range of f over which equation (1) is accurate is not clear. This is a question of some importance in that controversy exists as to the cause of discrepancies between equation (1) and optical measurements made on samples with $f > 0.3$. Some authors attribute the discrepancies to variation of ε_1 with particle radius[8] while others invoke various distributions of particle shape and orientation[9]. We consider that, before these two hypotheses can be meaningfully tested, proximity (higher order multipole) effects should be taken into account.

Fig. 1 Permittivity ε of a simple cubic array of perfectly conducting spheres as a function of volume fraction f. The order of the theory is indicated. $M = 1,2$, and 3 correspond respectively to the theories of Maxwell Garnett, Rayleigh (corrected) and Meredith and Tobias. $M = 4$ corresponds to equation (3) and $M = \infty$ to the exact curve.



In his classic paper[7] Rayleigh gave a second order treatment, with the aim of determining the region of validity of (1) for the cubic lattice. He took into account the effect of octupoles as well as dipoles (only 2^{2M-1} poles with M integral being allowed by symmetry). It is unfortunate that Rayleigh made two simple errors in the derivation of his final formula. The first of these (the omission of a factor of π) was corrected by Runge[10]; the second (the omission of a factor of 2/5 which arises in a partial differentiation of his equation (61)) is corrected here.

Lord Rayleigh's treatment was extended by Meredith and Tobias[11] to include the effects of poles of order 2^5. We have derived a formula which includes the effects of poles of order 2^7:

$$\varepsilon = 1 - 3f/D \tag{2}$$

$$\text{where } D = T_1^{-1} + f - b_1 T_5 f^{14/3} - c_1 T_7 f^6$$
$$- af^{10/3}\,\frac{[1 - c_2 T_5 f^{11/3} + c_3 T_5^2 f^{22/3}]}{[T_3^{-1} + b_2 f^{7/3} - c_4 T_5 f^6]} \tag{3}$$

Here

$$T_n^{-1} = \frac{\varepsilon_1 + [(n+1)/n]}{1-\varepsilon_1} \tag{4}$$

and

$$a = 1.3045 \tag{5}$$

$$\left.\begin{aligned} b_1 &= 0.01479 \\ b_2 &= 0.4054 \end{aligned}\right\} \tag{6}$$

$$\left.\begin{aligned} c_1 &= 0.1259 \\ c_2 &= 0.5289 \\ c_3 &= 0.06993 \\ c_4 &= 6.1673 \end{aligned}\right\} \tag{7}$$

Full details of the derivation of these constants (which included the re-evaluation of certain sums) will be presented later. Equation (3) yields the formula of Meredith and Tobias if c_1 to c_4 are replaced by zero. The corrected equation of Lord Rayleigh results if in addition b_1 and b_2 are replaced by zero.

Table 1 f_c and $f_{\max}$ as a function of M, the number of terms in the multipole expansion

M	f_c	$f_{\max}$
1	1.000	0.30
2	0.66505	0.41
3	0.64469	0.43
4	0.59250	0.46
10	0.54260	0.48
25	0.5279	0.515
50	0.5248	0.522
100	0.5239	

We have generalised the formalism in such a way as to permit its programming to any desired order of the multipole field expansion. Figure 1 shows the comparison of results provided by our programme for theories of increasing order M. Note that only the highest order theory has its divergence at the correct value of f. This point is illustrated more explicitly in Table 1, which also shows the upper limit on f, $f_{\max}$, at which the theory of order M is correct to within an absolute tolerance of 5×10^{-2}.

While a great deal of experimental information exists on disordered arrangements of spheres, we know of only two sets of measurements on simple cubic arrays of perfectly conducting particles[3,11]. These are compared with the results of theory in Fig. 2. The theoretical curve has been tested for convergence and is accurate to better than 1%. The complete agreement between theory and experiment is evident. It is interesting to note that the experimental measurement made closest to the touching point, with $f = 0.5161$, differs from theory by less than 0.1. We have shown numerically that to obtain this agreement we must include multipoles of order up to 2^{29}. This is a tribute to the remarkable accuracy of the measurement.

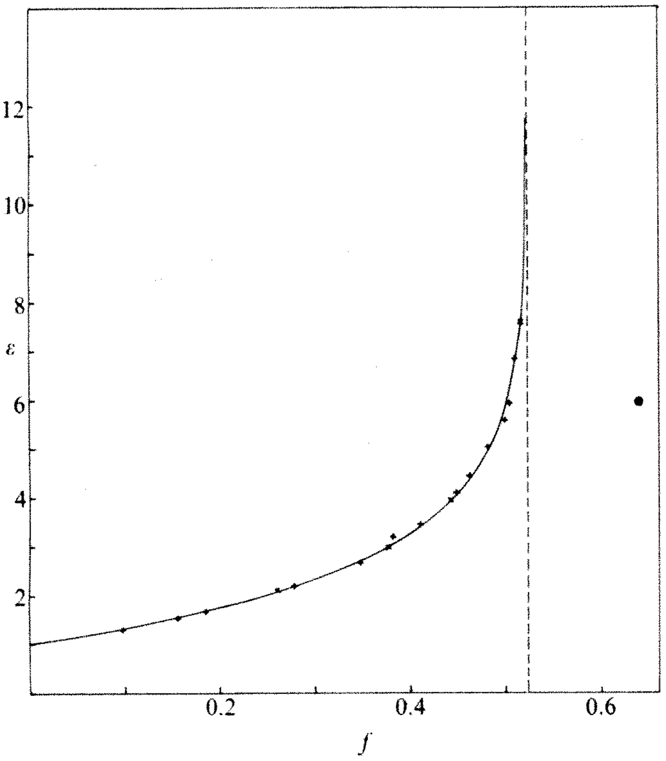


Fig. 2 Experimental measurements of Kharadly and Jackson (+) and of Meredith and Tobias (×) compared with the exact theoretical curve ($M = \infty$) of Fig. 1. The vertical dashed line corresponds to $f = 0.5236$.

Although we have discussed here only results pertaining to real permittivities of the spheres, the theory is general and its application to complex permittivities will be discussed later. We also envisage its extension to the close-packed lattices with the aim of devising a formula for close-packed random arrays. It is evident from the results above that such a formula is necessary to supplant the Maxwell Garnett equation (1) for dealing with random arrays having a volume fraction f greater than about 0.3.

This work was undertaken while one of us (R. C. M.) was the recipient of a Queen Elizabeth II Post-Doctoral Research Fellowship. We thank Professor H. Messel and the Science Foundation for Physics for the provision of facilities.

Surface circulation in Liverpool Bay

CONCERN over the influence of industrial and domestic effluents on the coastal waters of Liverpool Bay has led over the last decade to a number of physical, chemical and biological surveys[1–7]. Despite this intensive effort there is little that can at present be stated with confidence about the form and variability of the circulation (A. J. Bowen, T. R. S. Wilson and M. J. Howarth in ref. 1, vol. 3, pages 45–55). Conclusions derived from direct observations of residual currents (refs 2 and 3 and J. W. Ramster in ref. 1, vol. 2, pages 56–64) and indirect inferences from plankton[4] and chemical distributions[5–7] have combined to produce strong evidence in favour of either a clockwise[2,4] or anticlockwise (refs 3, 5–7 and J. W. Ramster in ref. 1, vol. 2, pages 56–64) surface residual circulation.

Direct observations of current direction and speed can be obtained over protracted periods from either continuously recording current meters (A. J. Bowen, T. R. S. Wilson and M. J. Howarth in ref. 1, vol. 3, pages 45–55; and J. W. Ramster in ref. 1, vol. 2, pages 56–64) attached to fixed buoys or from radio-tracked parachute drogues[8]. The obvious difficulty here is the sparse spatial distribution of synoptic data that can be obtained on anything other than a local scale. An alternative approach to elucidate the direction if not the magnitude of the circulation is to make use of the distribution of salinity, temperature and conservative chemical characteristics of the waters. The potential of utilising the intrinsic and quite often unique chemistries of the source waters of Liverpool Bay in any quantitative sense has largely been ignored[7]. This presumably is a consequence of the relatively large number of source waters that may significantly contribute to the area, and hence the number of different tracers required for the solution of any mixing model, together with the large number of samples that would have to be collected in this area of highly heterogeneous water chemistry[9] to provide comprehensive and unambiguous distributions.

Our objective has been to use the distributions of physical and chemical characteristics to determine the surface residual circulation pattern in Liverpool Bay. Dissolved concentrations of silicate, phosphate, nitrate, nitrite and ammonia were chosen as potential tracers in conjunction with salinity and temperature. The chemical species clearly do not meet the conservative prerequisite of a natural tracer during periods of sustained primary production and hence can only be used during the winter period. They can, however, be analysed by continuous on-line techniques[9,10] which provide greater definition of distributions and allow unambiguous interpretations that are not often possible with more traditional methods based on sampling at discrete stations.

Continuous records of the surface variability of these seven characteristics were obtained during a number of cruises on a comprehensive grid through Liverpool Bay during the winters of 1974 and 1975. Detailed descriptions of the observed distributions will be reported elsewhere. The number of contributory source waters and end member properties on each cruise were obtained by a combination of principal component analysis[9-11] and examination of the envelopes enclosing 21 X–Y diagrams generated by sequential plots of coincident data from the continuous records. On all cruises so far conducted the number of major sources identified has been smaller than the number of characteristics monitored, permitting a number of mixing model solutions from the same data set simply by varying the combination of tracers used.

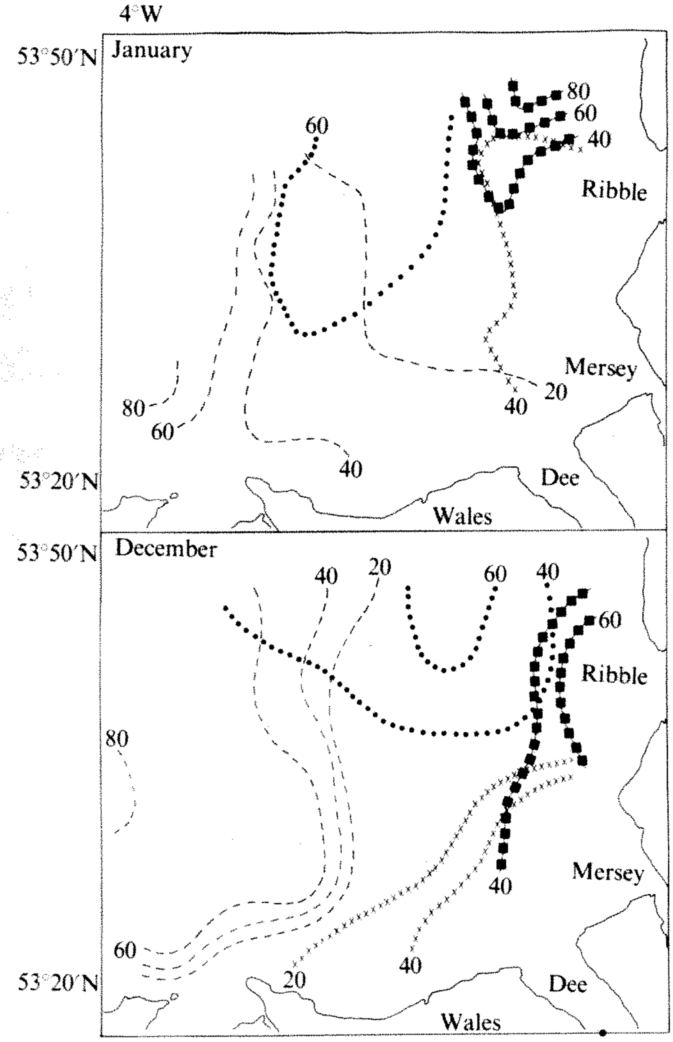

Fig. 1 During both January and December four major water types were identified. Mixing model solutions, showing percentile distributions are illustrated, both derived from salinity, temperature and silicate data. – – – Western boundary water; ●, northern boundary water; × and ■, fresh water.

Model solutions for the cruises so far conducted have produced two distinct extremes, observed during January and December 1975. The solutions are illustrated in Fig. 1, which shows that (1) in January, western boundary water encroached well into Liverpool Bay along the North Wales coast, in contrast to December when a marked physical discontinuity was observed at approximately 3°50′W. (2) In December a significant contribution from fresh water sources persisted along the North Wales coast, whereas in January a northerly transport of these waters was apparent, (3) in both January and December, a significant contribution to the waters in the centre of the bay originated from the northern boundary. Figure 2 shows the suggested circulation patterns. This novel approach to elucidation of the circulation pattern of Liverpool Bay demonstrates that either an anticlockwise or a clockwise circulation of the surface waters may be experienced during the winter period.

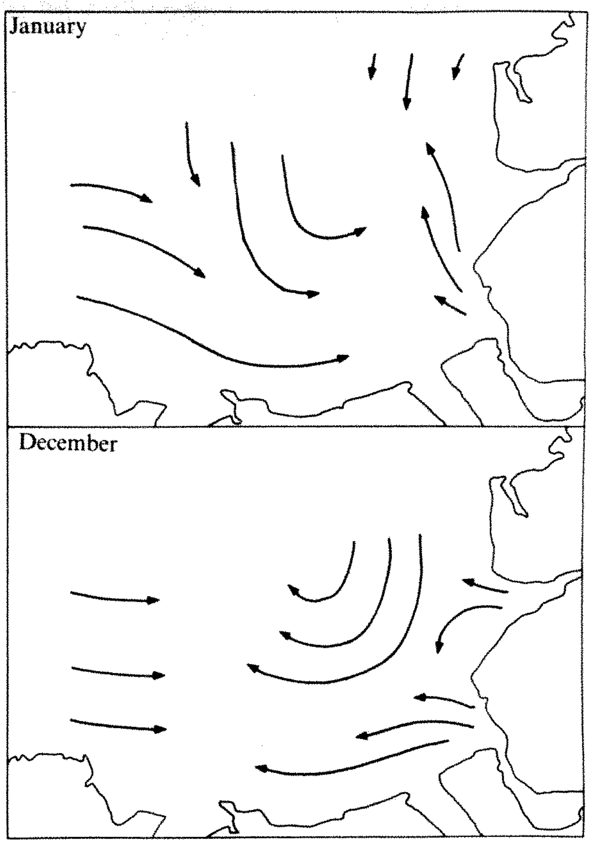

Fig. 2 Suggested surface circulation patterns in Liverpool Bay, January and December, 1975.

Of particular significance is the sharp contrast in the spatial distributions of potential pollutants associated with each circulation mode. Surface distribution maps exhibited high pollutant concentrations over an extensive sea area during periods of sustained clockwise circulation. We conclude that the replacement time of the fresh waters (particularly from the River Mersey with its associated industrial and domestic effluents) discharged into Liverpool Bay during periods of clockwise surface circulation is significantly greater than when the motion is anticlockwise. The possibility of deleterious consequences in the marine regime resulting from the terrestrial discharges is intimately related to the factors which initiate and subsequently maintain the clockwise circulation mode. Elucidation of these factors is the objective of continuing cruises.

Cyclonic ring formation at the polar front in the Drake Passage

THE first summary of geographical locations of the antarctic convergence (polar front) by Mackintosh[1] showed that >50% of the instantaneous locations of the front differed from the mean location by as much as ±50 km. Early hydrographic section work could not resolve the temporal or spatial fluctuations in the horizontal structure of the front. During FDRAKE 75 Gordon[2] observed comparable fluctuations in the frontal position in the Scotia Sea but again the spacing between sections was too wide. During FDRAKE 76 (refs 3, 4 and T. M. Joyce *et al.*, unpublished) the small scale structure of the polar front was studied in the Drake Passage. Two ships, the RV Thompson (University of Washington) and the Chilean naval vessel AGS Yelcho, combined efforts in the program which took place during the onset of the austral autumn. We describe here the evolution of the polar front between February 29 and April 5, 1976, a time span of ~5 weeks.

The polar front, in reality a transition zone between antarctic and subantarctic water masses[5], is most clearly revealed in vertical sections of temperature as that from our data shown in Fig. 1. South of the frontal zone there is a temperature minimum layer between 100 and 300 m. As noted by Gordon[6], this feature is insulated from seasonal heating at the surface. Within the frontal zone the minimum deepens abruptly and erodes splitting into multiple extrema of interleaving antarctic/subantarctic waters. Although numerous definitions of the polar front have been suggested[7], the operational definition used in our analyses is the presence of a well defined temperature minimum layer as delineated by the 2 °C isotherm. The selection of the 2 °C isotherm is somewhat arbitrary, but it does provide a convenient, consistent, and objective method for defining the position of the southern edge of the frontal zone.

Synoptic maps of the front have been produced with the combined data from the two vessels. While some artistry is involved in smoothing the observations, the horizontal density of measurements is sufficient to resolve the structure. A composite of these maps, Fig. 2, indicates that between March 10 and 24 a large meander developed in the polar front. This is verified by thermistor chain measurements (position shown in Fig. 2) from a subsurface mooring[8] in the vicinity and by the distribution of surface properties (not shown). The meander subsequently pinched off between March 28 and 30 into a cold, cyclonic ring of ~60–80 km diameter which then drifted to the NE at a speed of ~10 cm s^{-1}. The ring formation process is reminiscent of that observed in western boundary currents such as the Gulf Stream[9]. Continuous profiles of temperature and salinity show that the antarctic water types inside the ring penetrate to a depth of 2,500 m (Fig. 3), suggesting that much of the water column is involved.

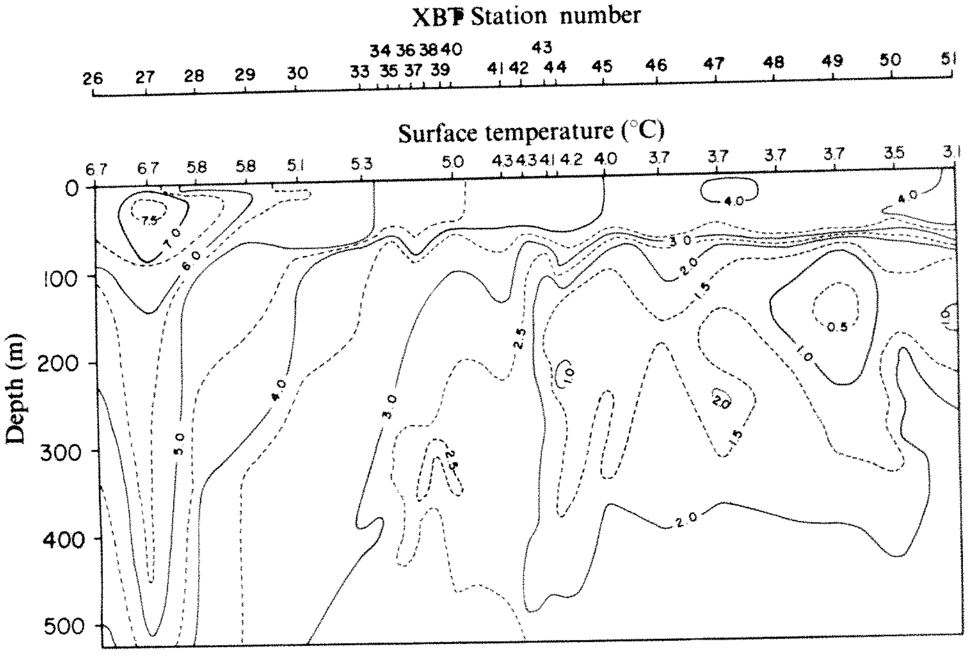

Fig. 1 XBT section across the polar front. Contours are in °C. Starting and ending positions for section are: XBT 26 (56° 44.8′ S, 65°30.4′W), XBT 51 (59°1.95′ S, 63° 2.5′ W).

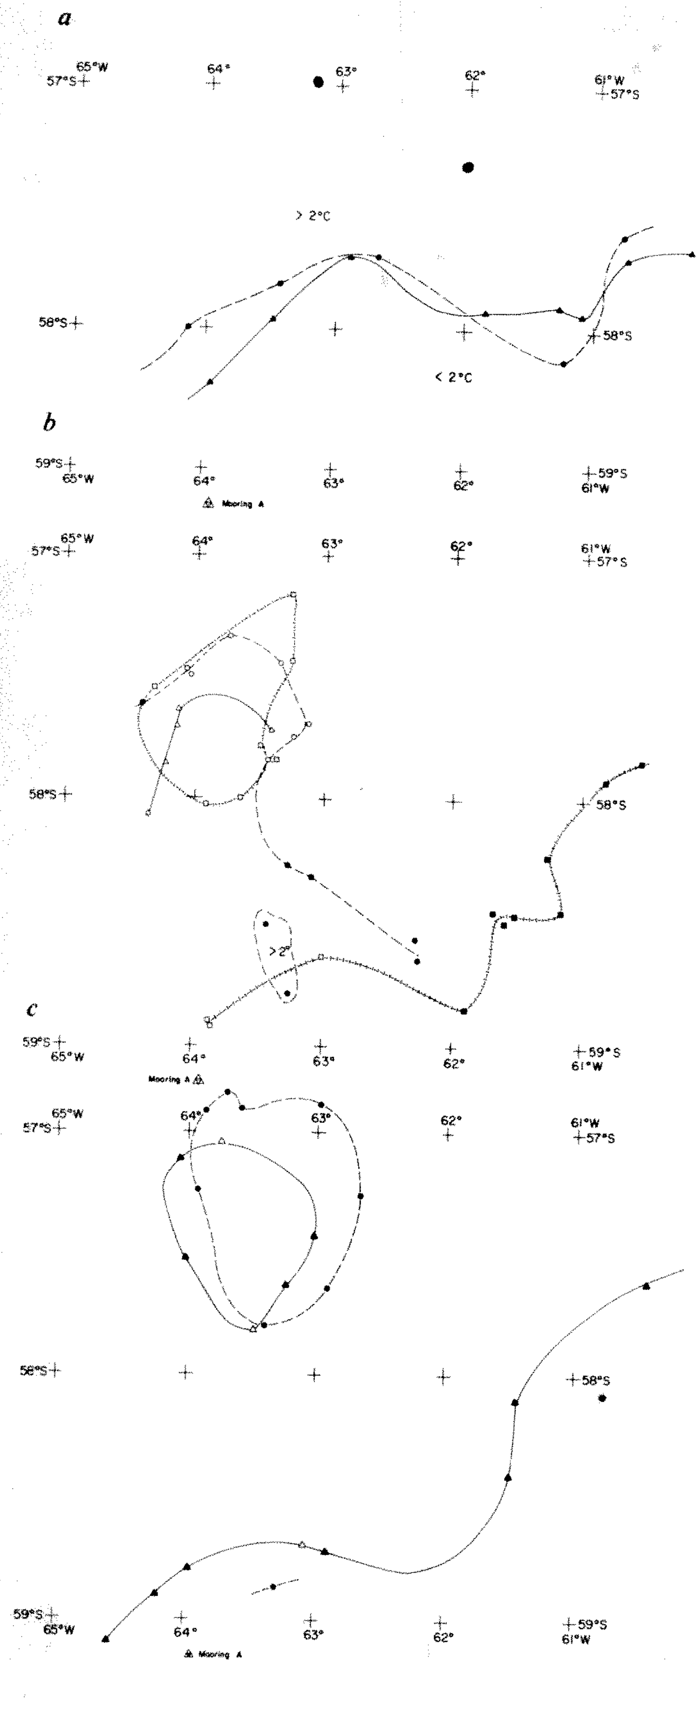

Fig. 2 Evolution of the polar front. Shown contoured is the boundary between antarctic waters and the interleaving regime of the frontal zone. Times are coordinated universal (CUT). *a*, February 29, 0130–March 5, 1830 △, ———; March 8, 1330–March 9, 1540 ○, — — —. *b*, March 16, 0000–March 20, 2359 △, ———; March 21, 0000–March 26, 2359 □, — — —; March 27, 0000–March 30, 2359 ○, + + + + .*c*, March 31, 0000–April 3, 2359 △, ———; April 4, 0230–April 5, 1315 ○, — — —. Solid (open) symbols represent observations from the Yelcho (Thompson).

Subsurface neutrally buoyant floats equipped with fins to react to vertical water motion[10,3], were tracked acoustically from the RV Thompson during the period of the ring formation. The track of these floats (Fig. 4) indicates that three of the four vertical current meters (VCM) were entrapped in the ring while the fourth continued unaffected to the NE. Horizontal velocities of the floats were 30–40 cm s^{-1}. The depth of each VCM at launch and recovery is indicated in Fig. 4.

A series of CTD (conductivity, temperature, depth) stations to 3,000 was made directly through the ring by the RV Thompson. These data, together with nutrients and dissolved oxygen need to be analysed before a complete description of the eddy properties (for example, circulation) can be determined. This work is in progress.

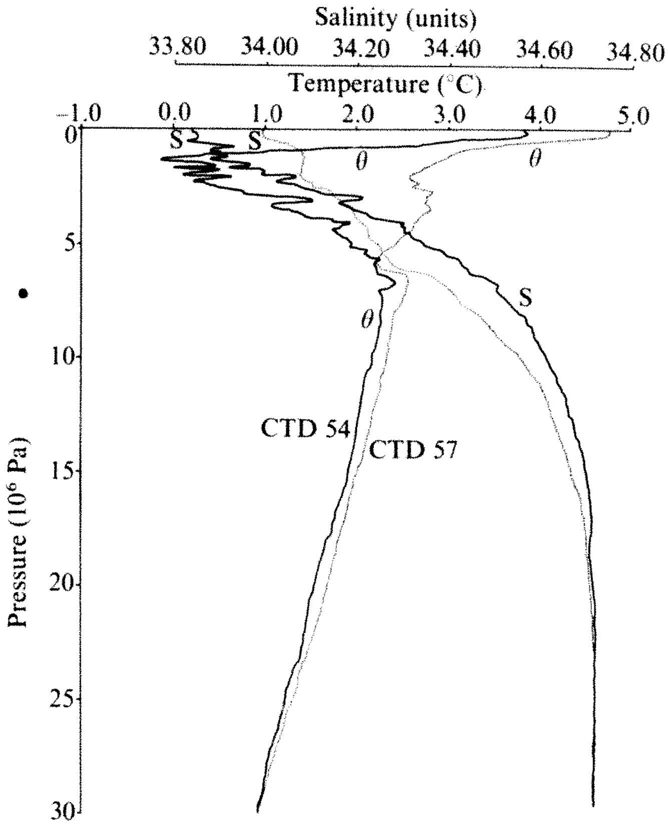

Fig. 3 Conductivity, Temperature, Depth (CTD) stations inside (54) and south, outside of the ring (57) but still north of the re-established polar front. Station locations are: 54: 57°39.9′ S, 63°51.0′ W, and 57: 57°59.9′ S, 62°59.8′ W.

The process described here can potentially transport large amounts of antarctic or subantarctic water across the front and may be fundamental to the understanding of heat and salt transfers towards the polar region. If the cold ring is reabsorbed into circumpolar current, the net transfer of properties will be less than if the ring were to remain detached, slowly decaying with time. Downstream of the Drake Passage, the circumpolar current system is highly constrained by the Scotia Ridge[11] which has only two large openings with a sill depth >2.5 km. It is interesting to speculate upon the fate of our cold water ring when it drifts into this rather formidable topography.

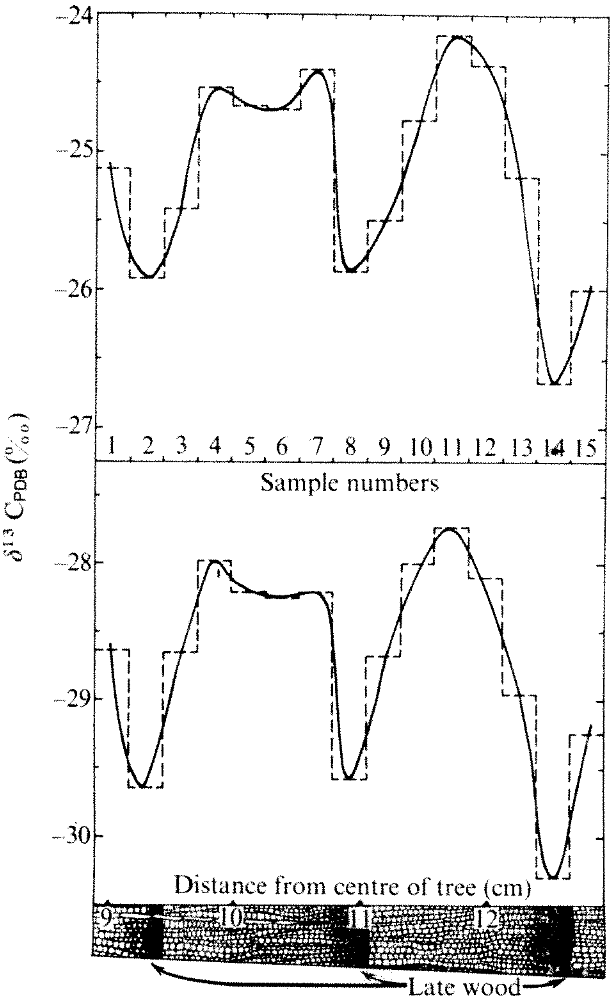
$^{12}C/^{13}C$ in cellulose and lignin as palaeothermometers

SEVERAL workers[1-3] have attempted to retrieve palaeoclimatic information from the $^{12}C/^{13}C$ ratios in tree rings. Their use of whole wood, however, has been unsatisfactory, in that the extractives are isotopically much lighter than cellulose[4] and vary considerably in content between heartwood and sapwood. Further, lignin is usually ~ 3‰ lighter than cellulose and it is well known from the extensive literature on the chemistry of wood that the lignin-to-cellulose ratio varies not only across one ring, that is, in late wood as compared to early wood, but up and down and radially across the tree[5]. The science of dendroclimatology is based on the observation that narrow rings represent a cold (or dry) year. In most conifers the amount of late wood remains relatively constant and it is the thickness of early wood that varies. A narrow ring would be expected to have a smaller proportion of early wood than a wide ring. The different proportions of lignin in the two rings would then lead to a different isotopic ratio for the whole wood. If whole wood is used the $\delta^{13}C$ measurements will reflect the relative proportions of lignin and cellulose. We therefore separated the lignin and cellulose from the wood before making $\delta^{13}C$ determinations, hoping that the temperature coefficients of their production reactions might be large enough to enable the temperatures at which the carbon was fixed from the atmosphere to be measured. We also wished to investigate the possibility that the difference in $\delta^{13}C$ between the cellulose and lignin might reflect temperature.

Preliminary experiments indicated that any temperature effects would be small; probably towards the lower limit of current mass spectrometric techniques. We therefore studied the annual rings of a specimen of *Pinus radiata* (Monterey Pine) which had grown in Hamilton, New Zealand. This tree has the advantage of laying wood all year[6], that is, over a temperature range of 10 °C. This enabled wood to be sampled that grew over a much wider temperature range than the range of post-glacial temperature fluctuations (perhaps 1–2 °C).

Fifteen samples over three annual rings were separated into cellulose and lignin using the conventional techniques of wood chemistry[7]. The samples were burned to produce CO_2 and this was measured in a Micromass 602C. The reproducibility of our measurements based on 12 separate combustions of the sample was ±0.04‰ (1σ). From Fig. 1 it can be seen that there is a depletion in ^{13}C for late (winter) wood as compared with early (summer) wood for both cellulose and lignin. Keeling[8] has measured the isotopic ratio of atmospheric carbon dioxide over the Pacific Ocean and shows that there is an annual fluctuation of ~ 0.3‰, the atmosphere becoming isotopically heavier in the late summer and autumn. This effect was attributed by Keeling to the activity of land plants[8]. The annual change we measured is of different phase and an order of magnitude greater than the change in the atmosphere. Thus we consider that the variations of $\delta^{13}C$ shown in Fig. 1 are caused by changes in air temperature affecting one or more of the biochemical reactions leading to cellulose and lignin. During the year in Hamilton both the monthly mean maximum daily temperature and the monthly mean daily temperature vary through a cycle with an amplitude of 10 °C. Thus we obtain a temperature coefficient for both cellulose and lignin of at least 0.2‰ per °C.

Fig. 1 Variation in the isotopic ratio of the carbon in cellulose (*a*) and lignin (*b*) across tree rings from *Pinus radiata*.



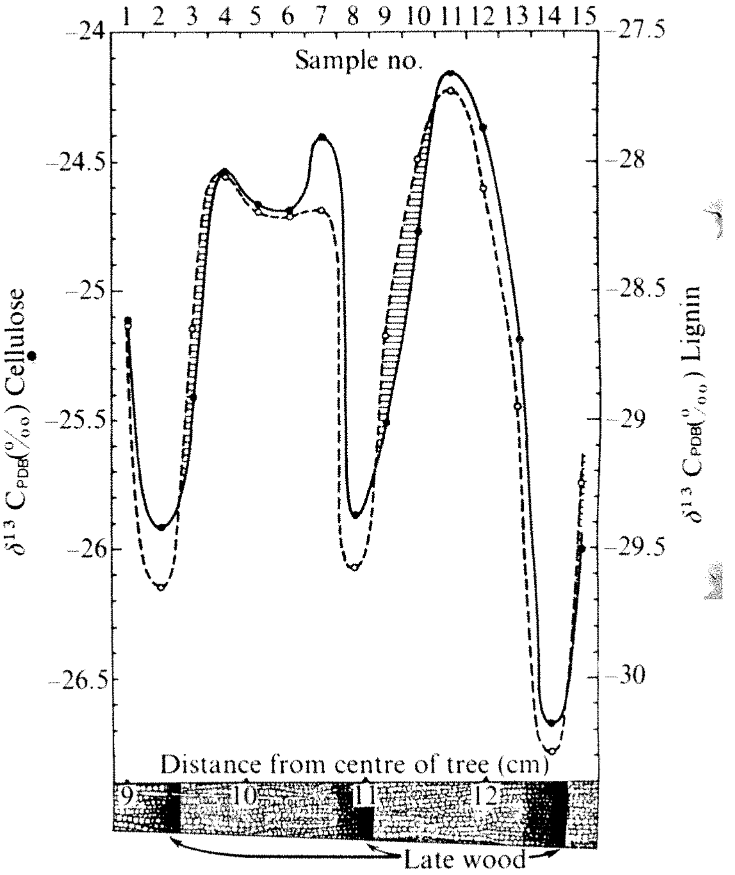


Fig. 2 Variations in the isotopic ratio of carbon across tree rings from *Pinus radiata*—a comparison between cellulose (—) and lignin (- - -).

Figure 2 presents the cellulose and lignin data superimposed. Several conclusions are evident. First, the amplitude of the $\delta^{13}C$ values of cellulose and lignin are very similar. This probably can be taken as evidence that the temperature dependent steps in the biochemical pathway leading to both cellulose and lignin are early in the sequence, probably in the leaves. Thus the temperature being monitored is that of the leaves rather than the trunk of the tree.

Second, although the cellulose and lignin curves are significantly different, these differences are probably too small to be of any use in palaeoclimatology with present mass spectrometric techniques. The third interesting result is the phase relationship between the cellulose and lignin curves. It is generally believed by plant physiologists that xylem cells are laid down and some time later lignified[9]. In Fig. 2 we can see the result of this secondary lignification, in that the lignin is significantly displaced in time and hence temperature with respect to the cellulose. This is excellent confirmation of the general interpretation given above.

If, as our results seem to indicate, the $\delta^{13}C$ values of cellulose and lignin vary with temperature, we may now ask if they will be of any use in determining past climate. Modern mass spectrometric techniques rarely measure $\delta^{13}C$ to better than 0.1‰ and few people have claimed to have made measurements with a standard deviation of better than 0.06‰ (0.3 °C). Modern mass spectrometers (such as Micromass 602C) can measure a sample of pure CO$_2$ with an s.d. of 0.02‰. The problem is associated with combustion of the sample, and in particular, impurities that contribute to the mass 45 peak in the mass spectrometer and hence limit the accuracy. We have found that with very careful combustion, great care in removing any water (which can form COOH$^+$ of mass 45) and by repeated sampling, one can make measurements with a precision of ± 0.02‰ (1σ), that is, measure temperatures to 0.1 °C. This would be adequate for palaeoclimatic studies provided one could assume that the δ^{13}C of the atmosphere has remained constant or is known.

This problem has been studied by Keeling[8,10] and others. Clearly there is an effect arising from man's combustion of fossil fuels since the Industrial Revolution. There are also localised effects in the vicinity of large industrial centres, and seasonal effects which have been attributed to the activity of land plants[8,10]. This latter effect would be averaged out if one sampled wood from a number of years. Another problem that must be avoided is that the atmosphere near the ground in a forest can be depleted in ^{13}C. This has been attributed to root and mycorrhizal respiration utilising photosynthates which are depleted with respect to the atmosphere. It has been observed that young plants growing in such a situation and therefore the internal rings of large trees are depleted in δ^{13}C (refs 1, 11, 12). Once the tree reaches maturity—perhaps because its foliage reaches the free atmosphere—the δ^{13}C content stabilises. Data from the inside rings of large trees will have to be treated with suspicion or the 'juvenile' effect—which is probably a smooth curve—corrected for. But, provided trees are chosen from suitable sites and corrections are applied for any man-made effect, it seems that δ^{13}C measurements on cellulose and/or lignin hold promise for obtaining past temperatures from subfossil wood. Since in some areas tree-ring records extend back annually for up to eight millennia, the prospect is exciting.

We thank Dr C. H. Hendy for helpful discussions and the New Zealand Universities Grants Committee for support. A.T.W. thanks the Climate Dynamics Program of the USNSF for support.

Precambrian evolution in a stratified global sea

HARGRAVES[1] postulates that continents on Earth emerged from a circumglobal ocean perhaps as recently as $1.0–1.4 \times 10^9$ yr ago. Without arguing the merits of the geological evidence supporting this theory, we suggest that the heuristic value and biological implications of this hypothesis are remarkable.

If such a sea existed some 3×10^9 yr ago, then life must have originated in this environment. In conformance, then, with current theories concerning the conditions necessary for life's genesis[2] we would expect high concentrations of both reduced organic carbon compounds and nutrients such as phosphate. Although physical conditions in such an ocean during the formative stages are arguable, surface heating by solar radiation and wind mixing would, in all probability, produce a warm low density surface layer. Without continents to obstruct horizontal oceanic currents or differentially heat the Earth's atmosphere, heat distribution on the planet's surface would be more uniform than at present. The high latitude generation of deep water would be less pronounced. While equatorial upwelling might still be expected, its magnitude is not clear and certainly the prominent upwellings now associated with continental margins would not exist. This primordial ocean, like a permanently stratified low latitude lake, would function essentially as two distinct subsystems—a warmer, wind-mixed epipelagic region and a cooler, poorly mixed, bathypelagic region. Once life began, nonconservative nutrients and reduced carbon would, as in present oceans, be removed from the surface waters by gravitational settling of organic remains.

Three implications emerge from these considerations. First, in the surface waters, evolutionary selection would favour cells with the high surface area-to-volume ratio essential for scavenging dilute nutrients. The food web, we suggest, was in gross outline comparable with that in the open oceans today[3]. Dissolved organic carbon compounds were anaerobically utilised by nanoplankton-sized saprobes and these in turn were preyed on by nano or small carnivores. With size restricted by nutrient concentrations, evolutionary selection for larger multicellular forms was absent and life remained at the unicellular level.

Second, we suggest that in light of the inverse relationship between body size and metabolic rate[4] and the lower energy yield obtained in anaerobic fermentation[5], primordial heterotrophs rapidly depleted the supply of reduced organic substrate in surface waters. On the assumptions that (1) initially the primordial ocean was 10% by weight reduced organic carbon[6]; (2) the epipelagic region extended to a depth of 100 m, (3) no reduced carbon was returned from bottom waters, and (4) the rate of organic carbon utilisation was comparable with that of heterotrophs in the oceans today, then reduced carbon reserves in surface waters could have been depleted within 250,000 yr. This suggests that in surface waters there was early evolutionary selection first for organisms able to utilise less reduced organic carbon[7], and then for photoautotrophs able to fix carbon dioxide. This argues for an early evolution of photosynthetic capability and the release of oxygen to the Earth's atmosphere and could account for the occurrence of chlorophyll in appreciable amount as early as 3×10^9 yr ago[8].

A third implication is persistence of anaerobic conditions in the bathypelagic region. Although a rate of photosynthesis comparable with that in the least productive regions of the present oceans could, in a period of 50,000 yr, yield a quantity of oxygen comparable with that in the present atmosphere, any buildup of atmospheric oxygen reserves would have little effect on the bottom waters. The continued input of reduced carbon from above, limited mixing, and the large volume of this lower region would militate against rises in oxygen concentration.

With the development of continental platforms able to obstruct horizontal ocean circulation, conditions in the primordial ocean would alter considerably. Upwellings developed along continental margins would elevate nutrient concentrations in at least limited regions of the photic zone. A consequent increase in both total energy fixed by autotrophs, and in cell size of autotrophs, would occur and in response to this latter change, the difference between carbon fixed by autotrophs and carbon utilised by autotrophs would increase. The net result would be an increase in the amount of energy available to heterotrophs and selection for metazoan forms. Platforms within 200 m of sea level may be required to initiate such upwelling[9].

At the outset selection might be for free swimming ciliated or flagellated forms structurally similar to the larval stages of most para or metazoan phyla. But with locomotor ability increasing in proportion to surface area and mass increasing in proportion to volume, a shift from planktonic to benthic modes of life would ultimately occur. Soft bodied, sessile, filter feeders, and burrowing, detrital feeders characteristic of marine benthic and neritic sediment would quickly colonise the elevated continental platforms.

Finally, evolutionary selection for large multicellular forms would come when persistent land forms emerged and regions comparable with the highly productive estuaries of today's Earth appeared. In response to the increases in nutrient concentration resulting from continental runoff, there would be selection for plants and animals able to withstand the rigours of a turbulent, near-shore environment. Large attached plants and hard-bodied animals evolved and, in a geologically brief period, colonised the newly emergent land forms.

Although the foregoing is only a sketchy outline, it is clear that if Hargraves is correct, we must rethink many ideas on biological evolution. Whereas conventional wisdom envisions life as slowly evolving until the early Cambrian and then blossoming to fill an array of previously sterile habitats, we would instead see evolution as a process rapidly generating forms to colonise each environment as it became available. The development of land masses and the evolution of life are viewed as intimately linked and the fossil record should provide dates for critical stages in Hargraves's chronology.

This vision of biological evolution in a stratified world ocean has important consequences in many other areas—among them the evolution of the terrestrial atmosphere and the origin of banded iron formation. For example, the Berkner–Marshall[10] view that Precambrian faunal development was retarded by lack of atmospheric oxygen is no longer viable. An oxygenated atmosphere nearly 3×10^9 yr before present is more consistent with fossil[11] and carbon isotope data [12,13].

Precambrian banded iron formation may represent periods of pronounced upwelling which for some reason (too brief in duration?) did not yield significant evolutionary development. Ferrous iron from upwelling waters would be precipitated on mixing with oxygenated surface waters. Seasonal variations in the intensity of coastal upwellings are not uncommon and could account for the banded character of banded iron formation. This mechanism is not grossly unlike that envisioned by others (for example ref. 14).

In conclusion it should be noted that the concept of a circumglobal sea, and the traditional view of early and persistent continents are mutually exclusive. Re-examination of data in the light of these different theories seems most appropriate.

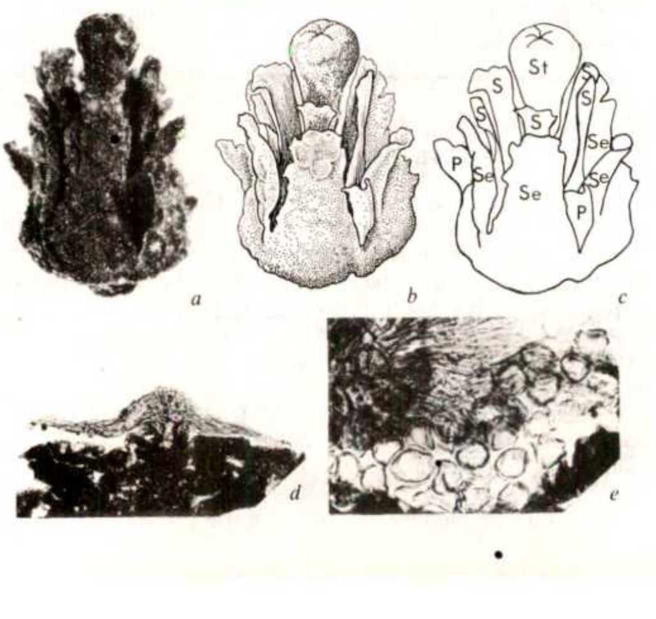
Dicotyledonous angiosperm flower from the Upper Cretaceous of Martha's Vineyard, Massachusetts

RECENT palaeobotanical studies on Cretaceous angiosperms, including those concerning the antiquity of the conduplicate carpel[1] and the first stages of the evolution of angiosperm pollen and leaf morphology[2] have contributed significantly to our knowledge of the group. However, the paucity of fossil flowers in the record[3] means that existing concepts of the nature of the early flowers of the angiosperms must be based on the comparative morphology of living forms. The discovery of the three-dimensionally preserved flower herein described, and its associated remains, is thus of considerable interest.

Upper Cretaceous plants have previously been described from ironstone concretions and sandy clays on the island of Martha's Vineyard, Massachusetts[4]. Mr Clifford Kaye of the United States Geological Survey called my attention to a more recently exposed occurrence of highly fossiliferous, dark-grey, sulphide-rich lignitic clay on the cliffs at Gay Head, at the extreme western end of the island. This clay has been dated by pollen analysis as earliest Campanian in age (Upper Cretaceous, about 75 Myr old) and is the source of the recently described gymnosperm cones *Pityostrobus kayei* and *Pseudoaraucaria arnoldii*[5]. Approximately 2,000 kg of this clay were collected, and subsequently disaggregated and sieved to concentrate the organic fraction. This was placed in hydrofluoric acid to remove adherent mineral matter, and finally washed. Examination of this material with the aid of a dissecting microscope revealed a diverse array of megaspores, gymnospermous staminate and ovulate cones, leaves and wood, and angiospermous fruits, seeds and flowers. These are all preserved as three-dimensional compactions, and retain a surprising degree of cellular detail. From this material, which forms the basis of a continuing and more detailed investigation, one particularly well preserved and distinctive flower was isolated, which is described in this preliminary report. It was carefully examined, drawn and photographed, and then embedded in paraffin by standard methods and sectioned at 10 μm intervals for examination with a compound microscope.

The 3.3-mm long flower (Fig. 1*a–c*) is apparently bisexual, possibly solitary, and borne on a short pedicel. The five sepals are basally united to form a shallow cup on which the five petals and five stamens are sequentially inserted, the stamens opposite the sepals. The calyx exceeds the corolla, but this may have been caused by the differential erosion of these two floral whorls. The gynaecium is capped by an inflated five-lobed stigma with a central depression. This five-part division is maintained in the cellular structure through the style to the ovary, suggesting the presence of five fused carpels. The compacted nature of the fossil precluded the determination of the number of locules

Fig. 1 *a*, Photograph of flower in lateral view; note the short pedicel (×12.8). *b* Drawing, looking into the flower at a slight angle (×12.8). *c*, Interpretative outline; St: stigma (the style below), S: stamen, P: petal, Se: sepal. Note that not all petals are present, and that one sepal is obscured. *d*, Median section through an umbonate, peltate trichome from the base of a stamen (×269). *e*, Tricolporoidate/tricolporate pollen (centre) and broken anther sac wall (top left) adherent to the base of one anther (bottom left and right) (×420).



and ovules present, their placentation, and the vascularisation of the individual carpels. No stylar canal is present. The laminar anthers lack whole anther sacs, but concentrations of thin-walled debris and pollen suggest that the sacs were embedded in the adaxial face of the stamen, on either side of the connective. The style, the pedicel, and the lower portions of the anthers are ornamented with umbonate, stalked, peltate trichomes which range from 120 to 150 um in diameter and are up to 20 μm thick (Fig. 1*d*). Abundant tricolporoidate to tricolporate pollen is found on the adaxial faces of the stamens (Fig. 1*e*), about the base of the gynaecium, and specifically localised on the five lobes, but not the interlobes, of the stigmatic terminus. The pollen is triangular in polar view, with the apertures borne at the angles. The exine is smooth. The average diameter of the grains is 10–12 μm. The large quantity of pollen adherent to the stigmatic surface implies that the flower was mature at the time of deposition.

The possibility that this flower represents a gymnospermous inflorescence seems remote, particularly in light of the pollen morphology, the presence of a clearly demarcated stigmatic region and the overall spatial relations of the parts. However, although the characteristics of this flower are distinctly angiospermous, their exact association does not seem to occur in any modern group, and attempts to place it in an extant angiosperm taxon have consistently failed. Indeed, the flower seems unique in its juxtaposition of putatively primitive characters (laminar stamens and its firm, resistant texture) with more advanced ones (connate carpels and styles, tricolporoidate/tricolporate pollen, and the small, presumably reduced, number of floral parts). This association of characters is perhaps most notable in that it is advanced beyond those postulated for the most primitive angiosperms[6,7], and thus reflects a "minimum" level of evolution achieved by the group by the Campanian. It is tempting to draw parallels between this fossil and various modern taxa. However, to do so would be to force it into the existing preconceived notions of angiosperm evolution, which are primarily based on the living flora.

It is thus deemed more productive to use the approach pioneered by Doyle and Hickey[2] with respect to leaves and pollen, in which the specimen is compared to other fossil material collected from older and younger horizons, as well as to material from the same horizon. The resulting "relative" taxonomy permits the recognition of trends within the fossil material which might otherwise be obscured. Continued investigation of the floral remains from this particular locality may reveal the presence of a distinctive grade of evolution, serving to elucidate the observed grouping of characters within this fossil as well as to indicate the broader trend of evolution within the dicotyledons at this time in their history.

I thank Mr Clifford Kaye for calling my attention to this locality, and for his interest and support; the selectmen of Gay Head, Massachusetts, for permission to collect at Gay Head cliffs; Professors Carroll Wood and Richard Howard of the Arnold Arboretum of Harvard University for taxonomic expertise, and Professors Elso S. Barghoorn and Rolla Tryon of Harvard University and Dr Leo J. Hickey of the Smithsonian Institution for comments on the manuscript. Figure 1*b* was drawn by Ms Karen Velmure, Arnold Arboretum. The research was supported in part by a grant from the Fernald Fund of the Gray Herbarium of Harvard University.

Effects of plant type, size of geographical range and taxonomic isolation on number of insect species associated with British plants

IN this communication we analyse the insects associated with higher plants other than trees, which have already received attention[1–5]. We are concerned with two basic problems. First, we ask how various types of higher plants differ in the numbers of species of insects which they support; we do this by comparing standard species–area curves[1,3,6,7] for five different sorts of plants. Then we consider how the "taxonomic isolation" of a plant, measured simply as the number of related species in the same genus and geographical region, might also influence the total number of insect species to be found on it. We find that while plant type and geographical range have a considerable effect, taxonomic isolation does not, except in the case of monocotyledonous herbs.

Our data come from the accounts of individual plant species given in the *Biological Flora of the British Isles*, published in the *Journal of Ecology* between volumes 36 (1948) and 61 (1973). We excluded the grasses (Graminae) because the insect data appeared to be particularly unreliable. (The entomological literature on which the accounts are based frequently records "grass" as a food plant, rather than the species of grass involved.) An arbitrary series of decisions, inevitably introducing some error, was also made about the accounts which listed no insect species for particular plants. Where an author used a term like "none observed" we included the record as a zero; where he used a term like "no information" we excluded it.

We are aware that many of the *Biological Flora* accounts are incomplete, but since they are compiled by numerous different authors over a long period this seems merely to have increased the variance in the data, rather than introduced systematic errors. It does mean, however, that our statements about the insects associated with different types of plants are based on relative and not absolute comparisons. The present geographical ranges of each of the plants within the British Isles, excluding Ireland (where there are grounds for believing that both the plant distribution and insect data may be less reliable) and the sites of known introductions, were obtained from the *Atlas of British Flora*[8]. The *Atlas* gives the distribution on each species on a presence or absence basis using grid squares of 10 km × 10 km ("10-km squares").

Within the *Biological Flora* data, five distinct groups of plants could be recognised (embracing the families and species listed in Table 1). (1) A group of 27 herbaceous, perennial (or in two cases perennial/biennial) dicotyledons. (The addition of a perennial fern with similar harbaceous growth form, and three creeping perennial but woody dicots made no difference to any of the conclusions listed below; these four species are distinguished in Table 1.) (2) a group of 10 perennial dicotyledenous woody bushes and small shrubs. (3) A group of 16 predominantly annual dicotyledons. Eight of these species are common agricultural weeds (seven annuals and one perennial). The other eight species are all annuals (or in one case annual/biennial) from various natural open or disturbed habitats, and "waste places". (4) A group of 14 monocotyledenous herbs. (5) A small group of four aquatic perennial dicots.

For convenience, these five categories will be referred to as "perennial herbs", "woody shrubs", "weeds and other annuals",

Table 1 Plant families and species in each of five groups recognised in our analyses

(1) *Perennial herbs* (Species in brackets also assigned to this category are a fern, and three creeping woody dicots.)	
Boraginaceae	*Myosotis alpestris*
Caryophyllaceae	*Silene nutans*
Cistaceae	(*Helianthemum chamaecistus*)
Compositae	*Chrysanthemum leucanthemum* *Cirsium acaulon* *Senecio jacobaea* *Succisa pratensis*
Cruciferae	*Draba aizoides*
Gentianaceae	*Gentiana verna*
Labiatae	*Teucrium scorodonia* (*Thymus* spp.) (*drucei* distribution data used)
Lobeliaceae	*Lobelia urens*
Papaveraceae	*Glaucium flavum*
Papilionaceae	*Hippocrepis comosa* *Lathyrus japonicus*
Plantaginaceae	*Plantago lanceolata* *P. major* *P. media*
Plumbaginaceae	*Limonium vulgare*
Polemoniaceae	*Polemonium caeruleum*
Polygonaceae	*Rumex crispus* *R. obtusifolius*
Polypodiaceae	(*Dryopteris villarii*)
Ranunculaceae	*Ranunculus acris* *R. bulbosus* *R. repens*
Rosaceae	(*Dryas octopetala*) *Sibbaldia procumbens* *Rubus chamaemorus*
Saxifragaceae	*Saxifraga hypnoides*
Urticaceae	*Urtica dioica*
(2) Woody shrubs	
Chenopodiaceae	*Halimione portulacoides*
Elaeagnaceae	*Hippophaë rhamnoides*
Empetraceae	*Empetrum nigrum*
Ericaceae	*Calluna vulgaris* *Erica cinerea* *E. tetralix* *Phyllodoce caerulea* *Vaccinium myrtillus* *V. vitis-idaea*
Rosaceae	*Potentilla fruticosa*
(3) Weeds and other annuals	
Balsaminaceae	*Impatiens parviflora*
Caryophyllaceae	*Corrigiola litoralis* *Spergula arvensis*
Chenopodiaceae	*Chenopodium album*
Compositae	*Anthemis arvensis* *A. cotula* *Sonchus oleraceus/asper*
Convolvulaceae	*Cuscuta epithymum* *C. europaea*
Cruciferae	*Cardaria draba* *Draba muralis* *Hornungia petraea* *Sinapis arvensis*
Papaveraceae	*Papaver rhoeas*
Plantaginaceae	*Plantago coronopus*
Scrophulariaceae	*Melampyrum cristatum*
(4) Monocots	
Amaryllidaceae	*Narcissus pseudonarcissus*
Araceae	*Arum maculatum*
Cyperaceae	*Carex flacca* *Eleocharis palustris* *Eriophorum angustifolium* *E. vaginatum* *Schoenus nigricans*
Juncaceae	*Juncus acutus* *J. squarrosus*
Liliaceae	*Allium ursinum* *Colchicum autumnale* *Endymion non-scriptus*
Orchidaceae	*Orchis purpurea*
Sparganiaceae	*Sparganium erectum*
(5) Aquatic dicots	
Loleliaceae	*Lobelia dortmanna*
Menyanthaceae	*Menyanthes trifloliata*
Nymphaeceae	*Nuphar* spp. (*lutea* distribution data used) *Nymphaea alba*

"monocots" and "aquatic dicots". Figure 1 shows their species–area relationships. S is the number of species of insect associated with each plant species, and A is the geographical range of that plant within the British Isles in 10-km squares. Because the axes are logarithmic, $S+1$ was used so that we could include those species of plants from which no insects were recorded.

The equations are:

Perennial herbs (Fig. 1*a*)

$$\ln[S+1] = 0.54 \ln A - 0.95 \qquad (1)$$
$$r^2 = 0.71;\ F_{1,29} = 69.57;\ P < 0.001$$

Woody shrubs (Fig. 1*b*)

$$\ln[S+1] = 0.45 \ln A + 0.005 \qquad (2)$$
$$r^2 = 0.85;\ F_{1,8} = 45.51;\ P < 0.001$$

Weeds and other annuals (Fig. 1*c*)

$$\ln[S+1] = 0.47 \ln A - 1.33 \qquad (3)$$
$$r^2 = 0.59;\ F_{1,14} = 20.32;\ 0.005 > P > 0.001$$

Monocots (Fig. 1*d*)

$$\ln[S+1] = 0.39 \ln A - 1.60 \qquad (4)$$
$$r^2 = 0.51;\ F_{1,12} = 12.64;\ 0.005 > P\ 0.001$$

No attempt was made to fit a regression line to the four points available for the aquatic dicots. They are illustrated as Fig. 1*a* for completeness.

Table 2 summarises a statistical comparison of the four regressions. None of them differs from any of the others in either residual variance or slope; they differ only in intercept. Each of the group of plants has a quite characteristic number of insect species associated with it, for a particular size of geographical range, in the sequence woody shrubs = perennial herbs > weeds and other annuals > monocots. Although the regression line for the woody shrubs lies above that for perennial herbs, the difference is not statistically significant. On the limited data available, the aquatic dicots seem to occupy a position somewhere between the weeds and other annuals, and the monocots.

We next tested the hypothesis[9-11] that taxonomic isolation reduces the number of species of insects associated with a plant, on the grounds that the "exchange" of herbivores between closely related plant species will be easier than "exchange" between unrelated species[11]. This assumes that, in general, closely related plants are biochemically and structurally more similar than less closely related ones, which does not seem unreasonable[12,13]. "Exchange" is used here to denote the aquisition of a herbivore guild on an evolutionary timescale. Figure 2 shows the residuals (R) derived from the appropriate species–area curves shown in Fig. 1 (equations (1)–(4)), plotted against the number of plant species in the genus (G) within the British Isles. (The number of species in the genus on a worldwide basis[14] yielded no sensible patterns.) Log G provided the best fits to these data, giving for:

Perennial herbs (Fig. 2*a*)

$$R = 0.19 \ln G - 0.32 \qquad (5)$$
$$r^2 = 0.07;\ F_{1,29} = 2.07;\ 0.25 > P > 0.1 \text{ n.s.}$$

Monocots (Fig. 2*d*)

$$R = 0.30 \ln G - 0.43 \qquad (6)$$
$$r^2 = 0.46;\ F_{1,12} = 10.28;\ 0.01 > P > 0.005$$

Only equation (6) is statistically significant. There was no relationship between R and G for either the woody shrubs (Fig. 2*b*) or the weeds and other annuals (Fig. 2*c*). The perennial herbs (equation (5)) show signs of the positive relationship predicted by the hypothesis, but this is not statistically significant.

If we view the number of species on a particular plant as a balance between colonisation and extinction, then geographically more widespread plants have a larger number of species associated with them because they are more likely to be found

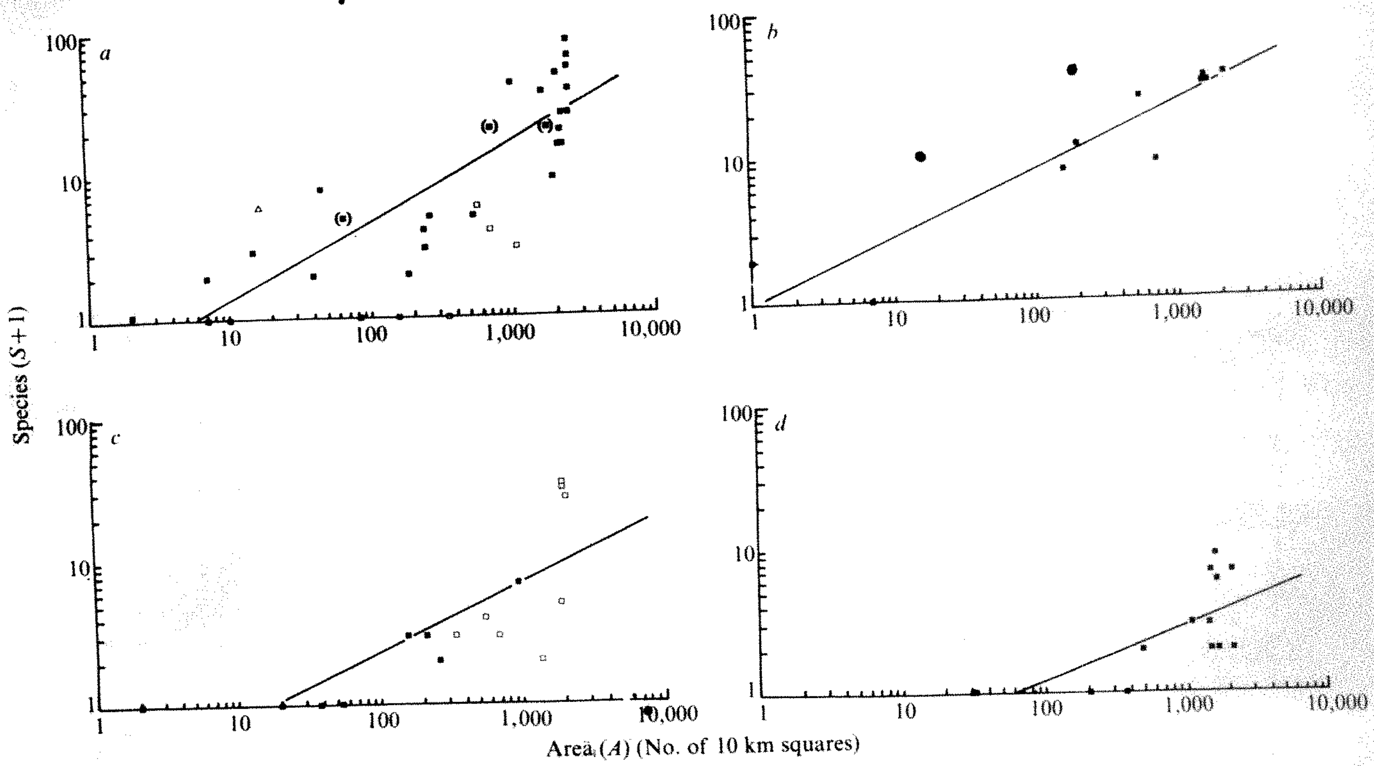

Fig. 1 Insect species associated with various groups of British plants, as a function of the size of the plant's geographical range (measured in terms of the number of 10-km squares occupied by the plant in the *Atlas of the British Flora*[8]). *a*, Perennial herbs. ■, Terrestrial herbaceous dicots; (■), creeping woody dicots; △, perennial fern; □, aquatic perennial dicots (not included in regression line). *b*, Woody shrubs. *c*, Weeds and other annuals. ■, Weeds; □, other annuals. *d*, Monocots (excluding grasses).

and colonised given sufficient time[1,3,4,9,11]. In Feeny's terminology[12], they are more "apparent". Unpredictability in time and space (weeds and other annuals) reduces "apparency" and increases the probability of extinctions; so does rarity. Hence the equilibrium number of species on rare and/or unpredicatable plants is reduced. Why monocots should have even lower equilibria is less obvious. We are inclined to the view that this is a function of their "architecture" with woody shrubs, perennial herbs and monocots forming a series of decreasing structural complexity. Structurally more complex plants permit greater niche diversification (both for competitor avoidance, and the avoidance of your neighbours' predators or parasites[15,16]) and hence have a bigger equilibrium species pool. Trees are even more structurally complex, and visual inspection of Strong's data for British trees[3] suggests higher numbers of associated species, area for area, than woody shrubs or perennial herbs. (A direct comparison is impossible, because Strong's equation does not fit his own results: also he included, and we excluded, Ireland from the plant-area measurements.) The complete series therefore appears to be trees > woody shrubs = perennial herbs > weeds and other annuals > monocots.

The paucity of insects on aquatic dicots (which fall in this series between weeds and other annuals, and monocots) is well known[17] and presumably reflects low colonisation (or high extinction) rates; why this should be however, is very uncertain.

Monocots excepted, there is no evidence to suggest that taxonomic isolation influences the number of species of insect associated with a particular plant. This may merely reflect the inadequacy of our data, our way of testing for taxonomic isolation, or some fundamental difference between monocots and other plants. For example, the total "pool" of insects adapted to feed on monocots may be so small that it has significantly impaired the probability that a taxonomically

Table 2 Statistical comparison of regressions 1–4

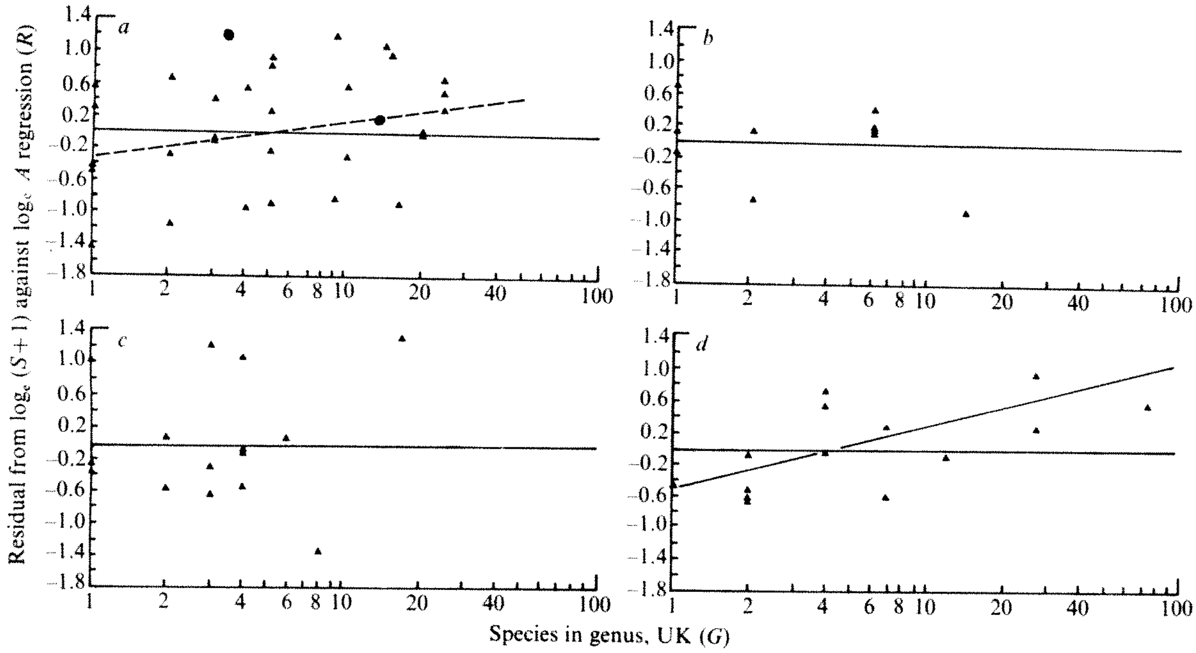

Fig. 2 The residuals from the fitted regression lines in Fig. 1, plotted against the number of species of plants within each genus in the United Kingdom. (The number of plant species in each genus is a measure of "taxonomic isolation".) *a*, Perennial herbs; *b*, woody shrubs; *c*, weeds and other annuals; *d*, monocots. Only the monocots (*d*) show a significant relationship.

isolated member of this group will be colonised over evolutionary time. With a larger total "pool" (like that on perennial herbs) the effects of taxonomic isolation have been lost. This viewpoint obviously demands that the insects which exploit dicots have a negligible probability of contributing to the monocot "pool". It also raises some important questions about what is meant by an equilibrium assemblage[3-5], and the time scale over which this should be measured. These problems are beyond the scope of the present note.

We thank the British Council for a travel grant to J.H.L., and Professor T. R. E. Southwood for helpful discussions.

Evidence, using radioactive phosphorus, of interspecific food exchange in ants

MEMBERS of many ant species exchange fluid foods within the colony[1-4]. Similar exchange between social symbionts, living as "slaves"[5] or "guests"[6] and their hosts, is also documented[1]. However, in non-symbiotic species, found in the same habitat or in distinctly different habitats, this phenomenon is usually overlooked. We document here that the food-transporting worker ant of one species offered carbohydrate food to the aggressive worker ants of another as a means of suppressing aggression in the latter, as in appeasement displays in higher animals. The workers of the aggressive red fire ant species, *Solenopsis invicta*, introduced into the southern United States in the 1930s but comparatively recently named[7], were invariably offered regurgitated fluids by indigenous species *S. geminata* and *Pheidole dentata* which had been fed earlier with ^{32}P-labelled 20% sucrose solution.

In 1.5 cm diameter, 1.5 cm wide glass cells, where the donors and aggressors could encounter each other quite often, a single donor worker offered the regurgitate to four aggressors within 15 s of their first encounter, and all the aggressors were offered food within 20–30 min. Such a food offer was made regardless of the aggressor's caste. Both the *Solenopsis* species are polymorphic and *P. dentata* is dimorphic. In addition to major and minor castes, the polymorphic species contained a gradation of medium-sized workers. Immediately following antennal contact between the donor species and the aggressor species, both opened their mandibles: the aggressor apparently to alarm its sister workers and to seize the body parts of the donor, whereas the donor acted thus to regurgitate a large drop of fluid between its mandibles. As the alien species became more aggressive, seizing the donor, stinging, and so on, the food-offering responses of the donor also intensified: the donor contacted the aggressor's antennal bases with its vibrating antennae and oriented the food droplet towards the aggressor (Fig. 1). When the donor was kept with workers of its own species, the workers contacted its antennal bases with theirs, in food solicitation. In some cases, food was offered only after the solicitors groomed the donor with their mouth parts in a ritualised fashion from legs up to the cephalic ventrum. The contrast in food-offering behaviour by one donor worker towards its own sister workers, and the aggressive workers of an alien species, suggested

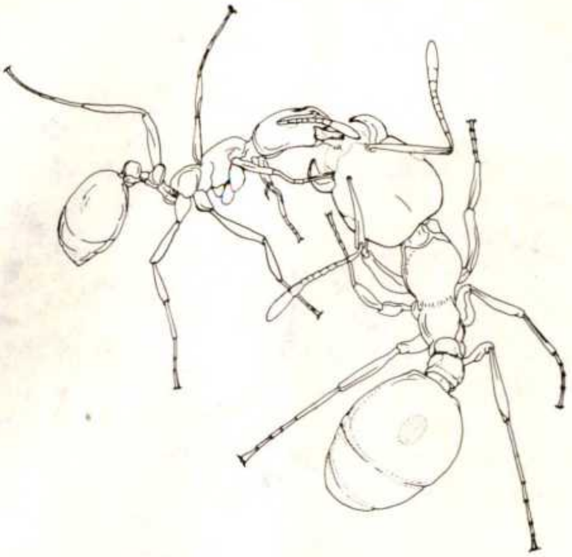

Fig. 1 Unusual interspecific trophallaxis between a donor of *Solenopsis invicta* (major worker with hatched spot on abdomen) and an aggressive solicitor minor worker of *S. geminata* drawn from actual photograph. The "appeased" solicitor touched the donor's mandibles with its forelegs and held antennae near head while feeding. The donor held its antennae in a W-shape and moved them to and fro while being solicited. The donors are fed on $^3H^{32}PO_4$ (specific activity 1.8 mCi ml^{-1}) in 150 g Gerber baby food jars for 2 h. They were made less mobile by exposure to CO_2 for 5–10 s and were surface decontaminated by passing through inactive NaH_2PO_4 solution[1]. The radioactivity was measured by using a GM-end-window (thickness 1.2–1.4 mg cm^{-2}) counting tube in conjunction with a Berthold Scaler Timer BF 22/25.

that in the latter case, the readiness of the donor to offer food reduced the aggression in the aggressor species.

In the southern United States, where *S. invicta* is regarded as a nuisance, it subdued under laboratory conditions the colonies of over 30 species, comprising six subfamilies. It killed twice its number of *S. geminata* and four times its number of *P. dentata* when their workers confronted each other in large numbers[8]. When the workers of *S. geminata* and *P. dentata* were presented to each other in the ratio of four aggressors to one donor, and *S. invicta* was a donor species, food transfer occurred. No sooner had the donor offered its alimentary fluid to the aggressors, than their aggressive frenzy diminished and the food was accepted. The food was aggressively solicited a number of times within the short period of 30 min. The workers that did not accept food were especially aggressive, that is they elicited mandibular attack, stinging, and so on. The alien workers accepted food and groomed themselves. In the laboratory, the donor showed escape behaviour by crawling on the glass cell. In nature, the aggressor's pause to eat and groom itself could make the donor's escape possible.

Variations in the distribution of food from major or minor caste donors to similar or dissimilar castes of aggressive solicitors, in all the three species, may be due to the differential aggressive element present in individuals or castes, and the individual's own food reserve. This explanation may hold true for less frequent food transfer from the workers of *S. invicta* to the workers of *S. geminata* or *P. dentata*, that is the aggressive element in *S. invicta* dominated that in the other two species (Table 1). An overt form of defensive behaviour in the major workers of *S. geminata* and *P. dentata* with the use of a novel alarm-recruitment system has been documented[9]. During the colony confrontation studies between *S. invicta* and two species of *Pheidole*, the guarding workers of *P. dentata* and *P. morrisi* exchanged food with the nest-invading *S. invicta* workers and delayed their invasion by 20–30 min (A. P. Bhatkar, unpublished).

Monomorphic species where workers exchange fluid food within the colony, such as a species of subgenus *Diplorhoptrum*, *S. pergandei*, and *Monomorium pharaonis*, escaped the attacks of *S. invicta* by slipping through their wide open mandibles. The workers of both these species are approximately half the size of the smallest *S. invicta* (smallest *S. invicta* 3.2 mm, largest 7.5 mm). During prolonged exposures (20 min–60 min), however, *S. invicta* obtained food by piercing the soft cuticle of slow moving, less aggressive donors. Similarly, otherwise aggressive woodland species with monomorphic workers (1.5 times as large as the largest *S. invicta* worker), *Aphaenogaster lamellidens*, fell victim to *S. invicta* due to diminished aggression and mobility in the donors. We may add that intracolonial exchange of fluid foods was absent in *A. lamellidens*.

Exchange of alimentary liquids (solutions, emulsions and suspensions) between colony members, including social symbionts, is usually termed "trophallaxis"[9]. If the scope of this definition is appropriately widened, the occurrence of food transfer in nonsymbiotic species of the type described above could very well be termed "interspecific trophallaxis". Interspecific associations in the ant colonies have one common denominator which is that ultimately they are all trophic in relation. The development of all forms of social symbioses among ant colonies, from plesiobiosis (nesting in proximity with little or no communication), xenobiosis (food sharing, keeping separate broods), to dulosis (one species robbing the brood of another and increasing its common worker force) and inquilinism (one species passing its

Food distribution from donor to recipients, and secondarily, among recipients was not normal. High s.d. was due to some workers receiving food repeatedly while the others in small amount. Experiments were conducted at 28 °C, replicated three or four times, and the exposure of one donor to four aggressive solicitors in each replicate was 1–5 h.

life cycle at the cost of other) seem to have interspecific food exchange as a driving force in their evolution. Such a phenomenon among phylogenetically and ecologically separate species is possibly an adjustment against competition even when they come together by accident, such as the red imported fire ant from Brazil and the Florida Myrmicinae, described here.

This research was conducted at the University of Florida, Gainesville, in 1972 when the authors were graduate student and visiting professor respectively.

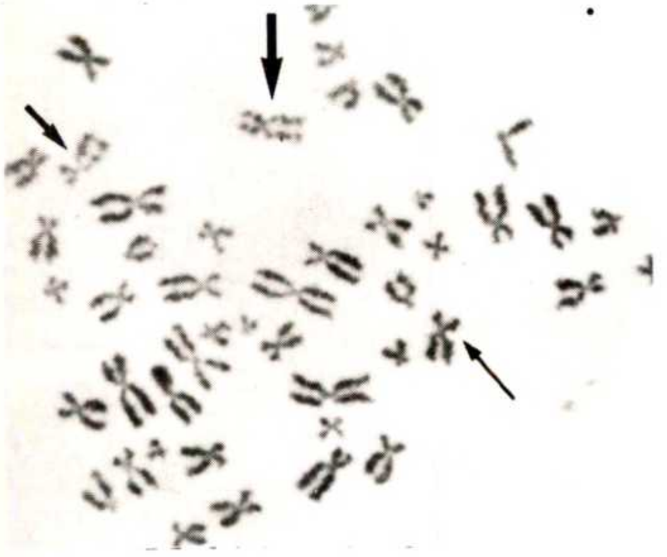
Presumptive evidence of two active X chromosomes in somatic cells of a human female

IN a female child with various morphological abnormalities and partial translocation trisomy X—karyotype: 46,XX,−22, +der(22),t(X;22)(q12;p11)mat—we have found evidence of two euchromatic X chromosomes in about 15% of metaphases from lymphocyte cultures. We believe this means that in these cells there were two active X chromosomes.

After treatment with BUdR (200 μg ml^{-1}) during the final 7 h of culture different patterns of decondensation were observed in individual metaphases. In 50% of cells an entire X and the long arm of the X/22 translocation chromosome, der(22), were decondensed (Fig. 1). In a smaller proportion of mitoses, however, the two normal Xs were of equal length, showing a reversed banding pattern, whereas the long arm of der(22) was highly decondensed (Fig. 2). In another cell line the der(22) and one whole X showed normal condensation, the other X being decondensed (Fig. 3). The rest of the karyotypes were uninformative.

Fig. 1 Type 3 cell. The thin arrow shows euchromatic X; the thick arrow, heterochromatic X, and the medium arrow, heterochromatic long arm of der(22) (verified by Q fluorescence).



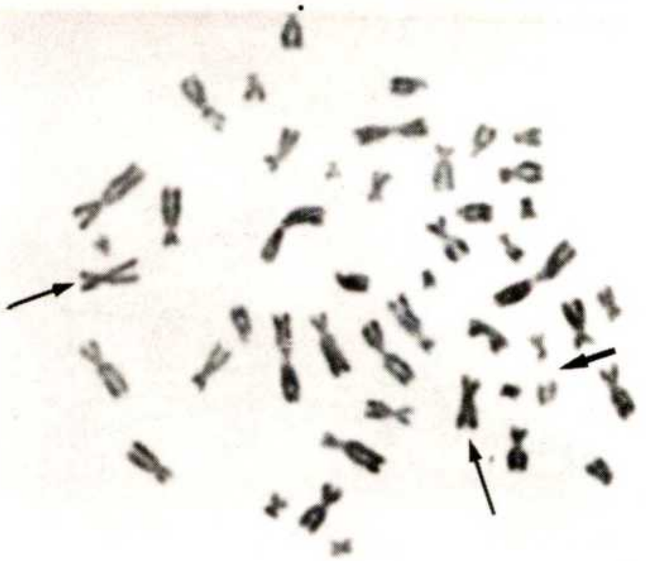


Fig. 2 Type 1 cell. The thin arrow shows euchromatic Xs, and the thick arrow shows heterochromatic long arm of der(22) (verified by Q fluorescence).

After treatment of blood cultures with ^{3}H-thymidine (1 μCi ml^{-1}) for the final 7 h of culture three different late replication patterns were observed. (1) In the majority of suitable metaphases one entire X and the der(22) were heavily labelled; (2) in a smaller proportion of cells only the long arm of the der(22) was late labelling, the two normal Xs showing only a few grains. (3) In a few mitoses one X was late replicating, whereas the other X and the der(22) showed an early pattern.

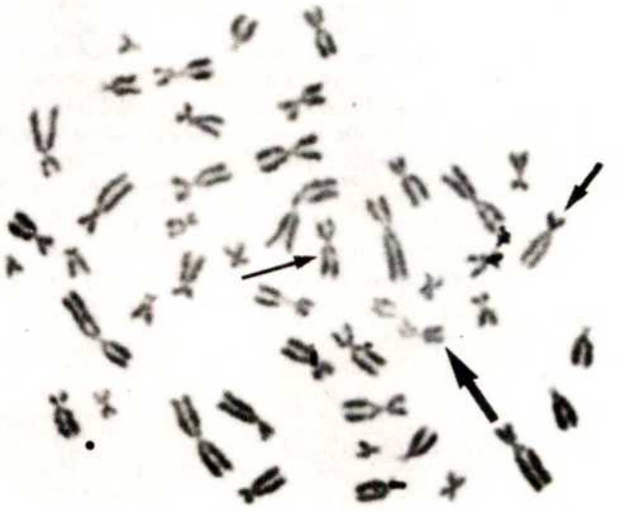

Fig. 3 Type 2 cell. The thin arrow shows euchromatic X; the medium arrow, euchromatic der(22), and the thick arrow, heterochromatic X (verified by Q fluorescence).

Percentages and sample sizes are summarised in Table 1. The different percentages of type 2 and type 3 cells found with BUdR and autoradiography respectively can probably be explained by the small sample size. (The uninformative observations are not entered in Table 1. They account for the differences between summed percentages and 100%.)

Four different sex chromatin patterns were found in buccal mucosa cells, hair root cells and fibroblasts (Fig. 4).

† Xq, Xq12 → Xqter.
‡ See text.

There were single normal sized Barr bodies, double Barr bodies of equal size, double bodies of different size and single small bodies. The latter are thought to be derived from the der(22) chromosome, consisting of Xq only, and the normal sized sex chromatin bodies are thought to be derived from the morphologically normal X. Two equal sized Barr bodies would then suggest the presence of cells with two equal sized heterochromatic Xs. This type of cell (type 4, Table 1), however, was never identified in blood cultures with either BUdR or ^{3}H-thymidine. The nuclei with two Barr bodies of apparently equal size were probably cells with one entire X and the der(22) inactivated, the difference in size between the two not being detectable in every interphase nucleus. The size of the Barr bodies in cases of Xq− or i(Xp) as well as Xp− has been reported sometimes to appear normal, for example as reported by Van den Berghe *et al.*[1] and Atkins *et al.*[2]. The most striking discrepancy between metaphases of cultured blood cells and sex chromatin findings in interphase nuclei was the relative paucity of nuclei with double bodies, especially in hair root cells and fibroblasts, compared with 50% and 76% of blood cells with one X and the der(22) inactivated (type 3, Table 1). It is well known, however, that in proven cases of triple X syndrome only a certain percentage of cells shows double Barr bodies, just as in normal females only between 20% and 50% of interphase nuclei are sex chromatin positive, varying according to the tissue examined and the method used. There is very good agreement with respect to cells with two active Xs (type 1, Table 1) and fair agreement for cells of types 1 and 2 taken together, allowing for the fact that some of the cells with one normal sized body are probably cells of type 3 with one X and the der(22) inactivated. It is also possible that the four cell types are present in different ratios in different tissues. Type 4 cells (Table 1) probably do not exist in lymphocytes. Whether they exist in other tissues or whether the recorded double Barr bodies of equal, normal size were Barr bodies derived from structurally different chromosomes (X and der(22)) corresponding to type 3 cells remains to be shown.

The mother of the patient had normal sex chromatin counts. She had the same translocation chromosome der(22) in addition to one normal and one deleted X, consisting of Xp, centromere and proximal Xq—karyotype: 46,X,t(X;22)(q12:p11). She had a normal phenotype.

At 6 months the child had failed to grow and gain weight and had deformities of head and face with low set ears, small lower jaw, upward slant to the eyes as in mongoloids, beaked nose, flat bridge of the nose, epicanthal folds, congenital heart disease and hypertonus of muscles. This phenotype cannot be explained solely by the partial trisomy X. It could be explained by monosomy 22 through spread of inactivation on the translocated 22. But the translocated 22 never showed any elongation or fuzziness or decondensation indicating inactivation (Figs 1 and 2) as shown for two X/autosome translocations by the BUdR method[3] and autoradiographically for an X/21 translocation[4]. In sufficiently stained metaphases with straight (neither bent nor twisted) chromosomes no label was seen over the short arm of the der(22) chromosome (Fig. 5) in neither cell type. If this should prove to be the case in other tissues, the reason for the malformations of the child must be sought in the gross genetic unbalance caused by noninactivation of

Fig. 4 Barr bodies in fibroblasts. *a*, Type 1, small Barr body; *b*, type 2, normal Barr body; *c*, type 3, small plus normal Barr bodies; *d*, type 4, two normal Barr bodies.

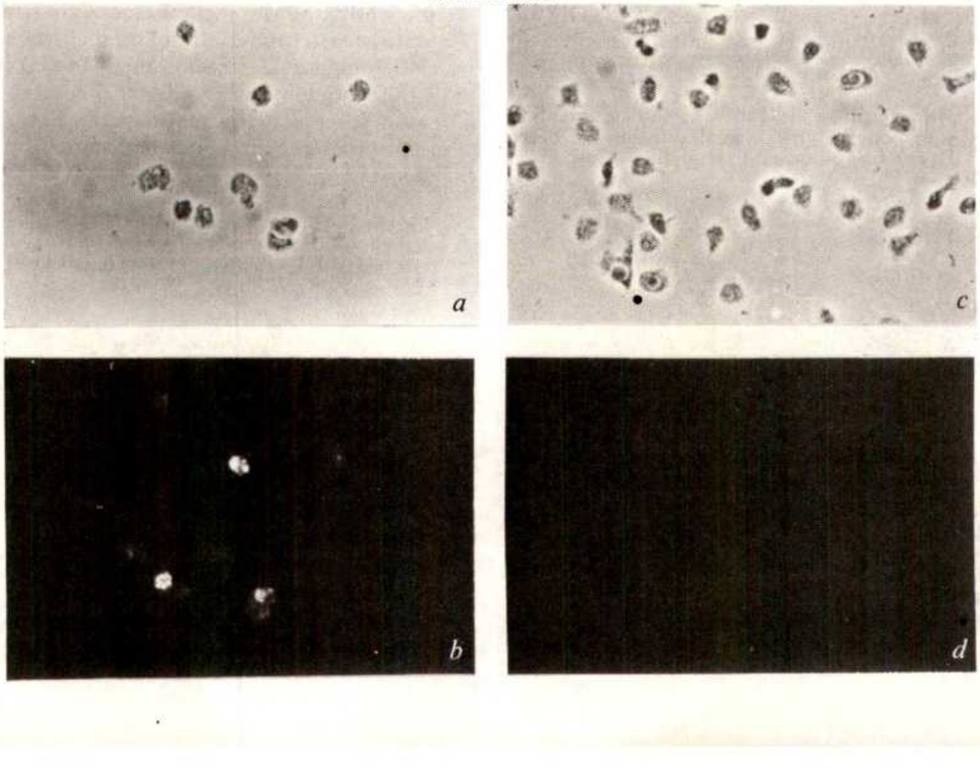
Pattern formation in the absence of polarity in *Dictyostelium discoideum*

MANY theories have been advanced as to how the spore–stalk pattern of the slime mould *Dictyostelium discoideum* is established. Without exception these envisage the polarity of the grex stage of the life cycle as a key factor in specifying the pattern. One group of theories[2–4] sees the combined influence of polarity and the grex tip as signalling positional information[5,6] which determines that the front cells differentiate into prestalk cells and the back cells into prespore cells. An alternative view is that pattern formation occurs by sorting out within the grex of cell types which are predetermined at an earlier stage of the life cycle[7–11]. Grex polarity is also a key factor in one suggested mechanism for sorting-out in that prestalk cells are seen as moving faster than prespore cells and therefore coming to the front of the migrating grex[8,12]. Because all these thories clearly suggest that pattern formation ought not to occur in circumstances in which the cell mass is unpolarised, we asked the question: 'Is polarity necessary for differentiation and pattern formation in *D. discoideum*?' We have found that a prestalk–prespore pattern very similar to that seen in the normal life cycle forms in spherical aggregates which, before pattern formation, have no detectable morphological polarity. We also describe the formation of unusual cyst-like structures from patterned spherical aggregates.

Spherical aggregates were formed by allowing axenically grown log phase cells of *D. discoideum* (strain AX-2) to adhere together in rotated suspension in phosphate buffer[13]. In such conditions cells begin adhering immediately, eventually forming spherical aggregates of about 100 μm in diameter. The cells became aggregation competent after approximately 8 h (ref. 14).

The first question we asked was whether differentiation of prespore cells would take place in such aggregates. This was tested by collecting aggregates at different times, dissociating them into single cells which were allowed to stick to a slide, and fixing and staining these with a fluorescein-labelled anti-spore serum prepared against the spores of *D. mucoroides* (modified from the method of Takeuchi), ref. 15 and D.F., and D.R.G., in preparation), (Fig. 1*a* and *b*). We found that specifically staining intracellular vesicles characteristic of prespore cells began to appear in a proportion of the cells between 12 and 13 h of shaking. By 17–18 h the vesicles stained more intensely and

Fig. 1 ×1,000. Cells dissociated from 18-h aggregates observed under phase-contrast (*a*) and under ultraviolet light (*b*), having been stained with specific anti-spore serum labelled with fluorescein isothiocyanate (FITC). Some of the cells show the development of specific prespore vesicles (PSVs). The same cells shaken more vigorously (*c*) remain single and on staining (*d*) show no specific reaction. *Dictyostelium discoideum* vegetative cells (strain Ax-2) were harvested from axenic growth medium[28], washed three times in cold distilled water, and resuspended in 0.0167 M phosphate buffer (*p*H 6.0) at a density of 10^6 cells ml^{-1}. Aliquots (4 ml) of the cell suspension were put into 25-ml flasks on a rotary shaker at 140 r.p.m. (radius of rotation ¼ inch: temperature 22 °C). The aggregates formed at 18 h were dissociated into single cells by trituration in cold distilled water. The single cells were suspended in standard salt solution[29] at 2×10^5 cells ml^{-1} and allowed to settle over and adhere to glass coverslips. Fixation and staining of cells with specific antispore serum was carried out as previously described[15]. For fluorescent microscopy cells were observed on a Zeiss Universal microscope, fitted with an HBO 200 mercury arc lamp, BG 38 and BG 12 exciter filters and Zeiss barrier filters 50 and 44. Cells treated with a control non-immune serum showed no specific staining. Cells were kept single and prevented from forming aggregates by shaking at 260 r.p.m. These cells were tested for aggregation competence at 8 h by allowing them to settle on to coverslips and looking for the formation of characteristic elongated shapes and development of end-to-end chain-like contacts between cells.



were present in a greater proportion of the cells. These vesicles seemed identical to the prespore vesicles (PSV) which have been identified in late aggregates and grexes when cells are allowed to develop in normal conditions on a surface (refs 15, 16 and D.F., and D.R.G., in preparation). The time of appearance of prespore cells in spherical aggregates was approximately the same (that is, 12 h after the end of the vegetative phase and 4 h after chemotactic aggregation) as in cells undergoing normal development (D.F., and D.R.G., in preparation).

When vegetative cells were kept single in suspension by vigorous shaking, they became aggregation competent after about 8 h even though they did not form aggregates. Would such cells also differentiate into prespore cells? Even after 36 h of shaking in suspension single cells showed no sign of staining with specific anti-spore serum though they remained viable (Fig. 1*c* and *d*). It seems that single cells are capable of differentiation to the aggregation stage but cell contact is an essential prerequisite for further differentiation into prespore cells.

Since morphological polarity of aggregates was not essential for prespore differentiation, we proceeded to ask whether the formation of a prespore : prestalk pattern could also occur in the absence of polarity. Fluorescent antibody staining of sections through 18 h aggregates showed no obvious patterning of the arrangement of stained and unstained cells (Fig. 2*a*). By 24 h, however, there was a clear spatial separation of the two cell types (Fig. 2*b*). Examination of many randomly sectioned aggregates showed the structure to be a mass of stained prespore cells partially surrounded by a cap of unstained cells. When 24-h aggregates were plated on to an agar surface they developed directly into normal fruiting bodies.

Because differentiation and pattern formation could proceed to a considerable extent within spherical aggregates by 24 h, shaking was continued for longer periods to see whether differentiation into mature spores and stalk would occur. We found that after 4 d of shaking, aggregates formed cyst-like structures unlike any morphological arrangement previously reported. These consisted of three concentric layers, an outer non-cellular coat, a layer of loosely packed cells and a central core of tightly adhering cells (Fig. 3*a*). Both the outer coat and the surfaces of the outer layer of cells exhibited specific staining with antispore serum. Cells in the central core were not stained (Fig. 3*b*). On the basis of phase contrast microscopy we concluded that neither of the two cell types in the cysts structurally resembled either the spores or the stalk cells of normal fruiting bodies. Examination of stages intermediate between 24 and 96 h revealed a progressive accumulation of fluorescent-staining material at the aggregate surface and a corresponding decrease in the number and intensity of staining of PSVs. We suggest that although mature spores were not seen in these cysts, the vesicles in the prespore cells release their contents to the cell surface in the same way as do prespore cells during normal culmination[16,17], and that this material moves to the outside where it forms the coat of the cyst. Cyst formation is being further examined by electron microscopy. 4-d cysts did not develop when simply plated onto an agar surface but gave normal fruiting bodies within 4–5 d when plated with a bacterial food source.

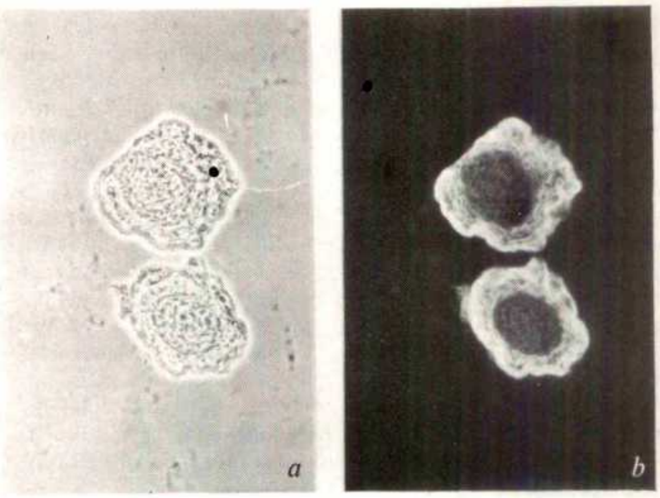


Fig. 3 Sections through 96-h aggregates under phase contrast (*a*) and ultraviolet light (*b*) having been stained with FITC-labelled anti-spore serum × 625.

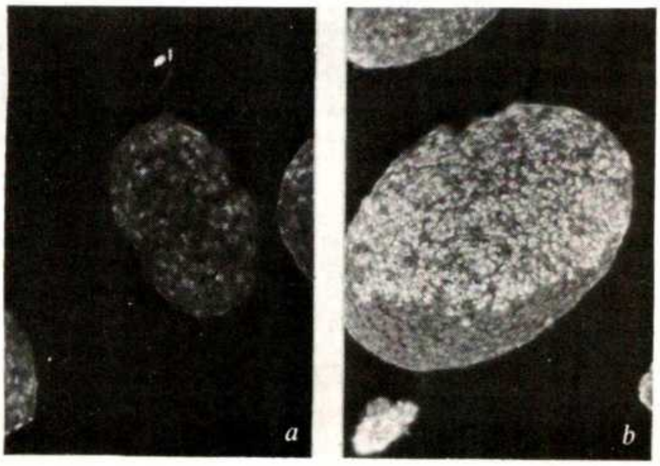
Fig. 2 Sections through 18 h (*a*) and 24 h (*b*) aggregates stained with FITC-labelled anti-spore serum and observed under ultraviolet light. Aggregates were settled out from phosphate buffer, fixed in 95% ethanol, dehydrated, wax embedded, and sectioned at 5 μm according to the method of Sainte-Marie[30]. Staining was the same as for single cells. *a*, × 1,250; *b* × 625.



The most important conclusion from these results is that differentiation and pattern formation, ostensibly similar to that found in the normal life cycle, can occur amongst *D. discoideum* cells in conditions where anterior–posterior polarity and grex tip formation are absent. The only necessary conditions for prespore differentiation which we can identify at present are (1) that the cells should be 12 h post-feeding and (2) that they should be in mutual contact. PSV formation may be added to a number of differentiative processes mediated by cell contact following aggregation[18,19].

Since there is no obvious spatial organisation in the early appearance of prespore cells, we suggest, in common with Takeuchi[15], that the cell types differentiate at random within the aggregate and then give rise to the pattern by sorting-out. (That spatially random differentiation can occur within populations of slime mould cells is shown by the random establishment of aggregation centres within a uniform field of amoebae[20]. Proof that prespore and prestalk cells can also differentiate at random requires further experimentation.) Although our observations do not provide definitive proof of sorting-out, they are consistent with such an interpretation, and there is good evidence that sorting-out of slime mould cells does occur[7–11]. In addition it is well known from extensive studies on vertebrate embryo cells that different cell types adopt the types of configuration which we have found by sorting-out within aggregates[21,22]. Our results are inconsistent with differentiation in position because we have never observed in 18-h aggregates in a region devoid of prespore cells comparable in size to the non-staining regions of 24-h aggregates.

We propose the following new view of pattern formation in the slime mould. It has been shown that during the normal life cycle, differentiation of cell types slightly precedes the formation of a grex tip[23], and so it may be suggested that pattern formation occurs by sorting-out which begins before tip formation and that it is the early prestalk region which gives rise to the grex tip. Viewed in this way, it is the prestalk–prespore pattern which generates the polarity of the cell mass rather than the polarity which generates the pattern. Pattern formation certainly precedes the migrating grex stage[24] but it remains to be determined at precisely what stage during the normal life cycle the spatial pattern actually begins to form. Such a view leaves unexplained the mechanism governing the numerical proportions of mature spore and stalk cells which are known to be present in approximately the same proportionate ratio irrespective of the size of the cell mass[25–27]. We suggest (and we know of no evidence which contradicts this view) that the method of proportioning is independent of the mechanism which determines the spatial arrangement of cell types and the polarity of the cell mass.

We thank Sherilee Taylor, Lynette Banham and Alistair Nicol for assistance. The work was supported by the Science Research Council. D.F. was an SRC Studentship holder. We thank Professor M. A. Sleigh for improving the manuscript.

Defective chemotaxis in monosomy-7

CELLULAR defects of chemotaxis are rare disorders[1]. Little is known about the cellular mechanisms of the chemotactic response, and in most cases the nature of the defect remains obscure. Singh *et al.* have reported defective chemotaxis in association with a chromosomal abnormality[2]. In their patient, bone marrow cells were tetraploid. In most cells a chromosome 16 was missing and there was an extra C-group chromosome. We investigated neutrophil granulocyte function in haematological disorders. Our results from a study of neutrophil function in five patients with monosomy-7 seem to suggest an association between this chromosome abnormality and defective chemotaxis.

Patients 1 and 2 had blood and bone marrow findings indicating preleukaemia[3]; acute leukaemia later developed in patient 2. Patient 3 had acute myeloid leukaemia known to have been preceded by a preleukaemic phase. Patient 4 had acute myeloid leukaemia when first seen, and patient 5 had subacute myelomonocytic leukaemia. Patients 1 and 3 had distinctly increased susceptibility to bacterial infections, mainly pneumonias and abscesses. Patient 2 also suffered from repeated febrile episodes probably of infectious origin, but no conclusive evidence of infections could be obtained. Since defects of leukotactic function occur in chronic and acute bacterial infections[4,5], our tests were performed at least 1 week after the disappearance of any sign of infection. Patient 4 had been treated with cytostatic agents before testing, but not within 10 d before the experiments.

Chemotaxis was tested in patients 1, 2, 3 and 4 by a modification of the Boyden method[6] and in patient 5 by another modification[7] of the same. In the former method the results are expressed as the average number of cells per high power field that have migrated through a Millipore filter in 3 h, in the latter as the distance which the leading front of cells has migrated within the membrane in 1 h.

Assay conditions: patients 1, 2, 3 and 4, cell concentration was adjusted to 2×10^6 neutrophils ml^{-1}, and 10% pooled human serum was used in the cell suspension throughout. Modified Boyden chambers[6] were set up in triplicate. 30% heat-inactivated (30 min at 56 °C) or zymosan-activated (30 min at 37 °C) serum was used in the lower compartment, as indicated in the table. Hanks' solution was used as the medium. The cells were allowed to migrate for 3 h at 37 °C. Results are expressed as the average number of neutrophils per high power field (×400) on lower surface of Millipore filters (3-µm pore size) separating the upper compartment of the chamber from the lower one. Cells were counted in ten high power fields on each filter. Patient 5, cell concentration was adjusted to 1×10^6 neutrophils ml^{-1}. No serum was used in the cell suspension. 10% serum was added to the attractant compartment as indicated. The cells were allowed to migrate into the filters for 55 min towards casein (5 mg ml^{-1}) or serum, and for 90 min towards Hanks' solution, after which the leading front[7] of the cells was determined in five fields of each of six filters. The mean ± 2 s.e. of our normal material (40 individuals) for migration towards Hanks' solution is 20.7±3.7 µm, and towards casein 99±18 µm.

*Mean ± 1 s.e. of ten high power fields in each of three filters.

†Mean ± 1 s.e. of five determinations in each of six filters.

† Normal karyotype.
In all patients the karyotypes of leukoagglutinin-stimulated peripheral lymphocytes were normal.

Casein is used as a chemoattractant in the latter modification in addition to serum. The concentration of mature neutrophils (band and segmented) was constant in all experiments.

Our method for bone marrow chromosome work has been described in detail previously[8]. The routine method for banding practised in all cases was Giemsa staining of trypsin-treated slides. Q- and C-banding was performed in selected cases.

The response of cells from patients 1, 2, 3 and 4 to zymosan-activated serum was clearly inferior to that of control cells (Table 1). Good chemotactic activity could be developed with patient sera. These results indicate a cell-associated defect of chemotaxis. Owing to a switch to a new method which also allows the measurement of the random migration of cells, the results of patient 5 are not quantitatively comparable with the others. A possibly reduced chemotactic response was seen in this case, also. The random migration (Hank's solution in the attractant compartment) of the patient's cells was not clearly different from that of control cells. The patient's serum behaved like normal serum. The analysis made so far does not allow us to make conclusions about the true nature of the defect, which might be in the stimulation of migration by chemoattractants (chemokinesis), or in detecting the chemotactic gradient (chemotaxis).

Monosomy-7 is one of a number of non-random chromosome abnormalities occurring in disorders of the human bone marrow[9]. We have diagnosed five examples of this abnormality (Table 2). The occurrence of a cellular defect of chemotaxis, which itself is a very rare disorder, in at least four of the five can hardly be coincidental. The question arises whether the defect is due to the chromosome abnormality itself or whether it is caused by the disease. All the patients had overt leukaemia or preleukaemia. We have investigated about 30 other patients with similar diseases, many of whom had various chromosomal abnormalities[10], as well as about 40 patients with infection problems, and found a cellular defect of chemotaxis in only one additional case. This was a patient with preleukaemia and trisomy-8, but in another patient with preleukaemia and trisomy-8 chemotaxis was normal[10]. Thus the incidence of a chemotactic defect in monosomy-7 seems to be very high compared with other patients with similar diseases.

The present results suggest that monosomy-7 is intimately associated with defective response to chemoattractants. Although the nature of the association and the causal relationships are obscure, it seems reasonable to assume that chromosome-7 carries a gene or genes important for the chemotactic or chemokinetic response of neutrophils. This phenomenon may be similar to the loss of the Colton blood groups in monosomy-7 (ref. 11).

Age-dependent surface marker on haemopoietic stem cells

HAEMOPOIETIC stem cells, intravenously injected into lethally irradiated mice, form colonies in their spleens (colony-forming units in spleen, CFUS)[1]. This is a clonal assay[2]; CFUS form the precursors not only of red cells, granulocytes and platelets[3] but also themselves (self-renewal)[4]. Rosendaal *et al.*[5] reported that five spaced doses of hydroxyurea yielded femoral CFUS with a self-renewal

Table 1 Cellular products of the graft of circulating CFUS from anaemic mice

Normal, 3-month-old female BALB/c mice were the donors of the circulating CFUS used in these experiments. To increase the number of circulating CFUS mice were rendered anaemic by three consecutive daily subcutaneous injections of phenylhydrazine (Ajax Chemicals, Sydney, 1 mg per g body weight in neutral normal saline) and bled by cardiac puncture on the fifth day[7]. CFUS in blood were partly separated from red cells by dilution (1:1 normal saline) and centrifugation (800*g*, 20 min, RT) over a layer of Isopaque–Ficoll (Nyegaard, Oslo and Pharmacia, Uppsala, specific gravity 1.073). The layer of mononuclear cells at the plasma–Isopaque junction was collected. There was no detectable loss of CFUS with this technique. CFUS were exposed to NRS or adsorbed (BALB/c liver, red cells and thymus) RAMB[8], then complement (fresh frozen guinea pig serum) and finally washed before intravenous injection into recipients. Twice as many RAMB-treated cells than NRS-treated cells were injected so that the number of spleen colonies in recipients was about equal. Recipients (male BALB/c mice) were irradiated before grafting (20 per group) (700 R, 230 kVp, HVL ʟ mm Cu, 146 R min^{-1}, TSD 50 cm, Maximar) and received intravenous ^{59}Fe as the citrate 8 d later (0.5 μCi per mouse, ferric citrate, specific activity 100 μCi per 9.7 μg Fe). Half of each group was killed 10 d after grafting, cardiac blood was taken for estimation of the erythrocyte repopulating ability (ERA)[11] and spleens were taken for DNA estimation and colony counts[12]. 12 d after grafting the remaining mice were bled, killed and their spleens were collected for assay of CFUC and CFUS. CFUC were grown in α medium (Flow)–0.3% agar (Difco, Bacto Agar) for 14 d[9]. A single cell suspension of each spleen (passed through a sterile stainless steel sieve and gauze) was seeded—1/30 of an irradiation control spleen and 1/58 of a RAMB or NRS spleen. Dishes containing 5,000 normal nucleated myeloid cells were stimulated with the same colony-stimulating factor in the same culture and formed 100 colonies per dish. Secondary CFUS per original colony were assayed in pooled groups (irradiation control, RAMB and NRS, 10 mice per group).

capacity three times greater than that of untreated mice. A generation-age hypothesis was proposed as an explanation: the way the population of CFUS in the animal is organised to form blood is based on the generation-age of each CFUS after its origin in the animal. Younger stem cells have undergone fewer generation-ages so their capacity for self-renewal is greater. As stem cells age, the chances of their progeny being CFUS diminishes and the likelihood of their being cells committed to form red cells, granulocytes or platelets increases. It should be possible to demonstrate differences between stem cells with a reduced capacity to form themselves and those whose capacity is greater. I report here experiments with CFUS from the blood of anaemic mice treated with phenylhydrazine (PHZB CFUS)[6], whose capacity for self-renewal is known to be reduced[7].

PHZB CFUS were exposed to rabbit-anti-mouse-brain serum (RAMB, anti-CFUS serum)[8], or control normal rabbit serum (NRS) and then complement before grafting. The average NRS-treated PHZB CFUS formed four times more CFUS and twice as many colony forming units in culture (CFUC, committed precursors of granulocytes, progeny of CFUS)[9] and red cells than the average PHZB CFUS which had survived exposure to RAMB (Table 1). If allowance is made for the fact that 60% of the original PHZB CFUS had the RAMB determinant the differences were greater, threefold (CFUC and RBC) and sixfold (CFUS).

It is interesting that this same batch of RAMB killed 75% of normal bone marrow CFUS but only 50–60% (in different experiments) of PHZB CFUS. Furthermore, this RAMB had no effect on CFUC, progeny of CFUS, exposed to it before plating.

These results indicate that there are differences in the expression of the RAMB determinant between circulating stem cells with different capacities for self-renewal.

If the generation-age of stem cells were one of the ways in which blood formation were organised, it is appropriate to consider how that might be ordered in the animal. A distinction would have to be made between older and younger stem cells—an age-dependent surface marker on them might be one such means. Thus, as the stem cell aged, the expression of a receptor on it could diminish. Till has pointed out[10] that RAMB, which is expressed on some stem cells but not on CFUC, is a candidate surface marker. These results are compatible with his proposal. Experiments are in progress to elucidate the function of the RAMB determinant in the animal.

I thank Julie Kerr for assistance and Dr George Hodgson for stimulating discussions.

Serum and hormonal regulation of the "resting-proliferative" transition in a variant of 3T3 mouse cells

3T3 CELLS are embryonic mouse fibroblasts established in culture[1]. Serum depletion or "step-down" causes them to enter a "resting" state, which they leave on restoration of serum or "step-up", entering the "proliferative" state[2–4]. This transition between resting (also called G$_0$, A or R) and proliferating states seems to be the critical step in cell growth control[5–7]. Its study has been aided recently by several observations on extracellular growth regulators for 3T3 cells, for example the discovery of a new pituitary growth factor[4,8], growth stimulation by glucocorticoids[4,9] and interactions between pituitary factor and classical hormones[10–12]. Further studies would be greatly helped if variants or mutants of 3T3 with different growth responses towards hormones could be isolated. Here we report our finding of the variant ST1 which is inhibited by glucocorticoids, unlike 3T3 cells whose growth is stimulated by glucocorticoids[4,9] (growth of fibroblasts is normally inhibited by glucocorticoids[13]). In this paper we discuss the value of this new cell type for studies of the resting–proliferative transition; elsewhere we shall report how the

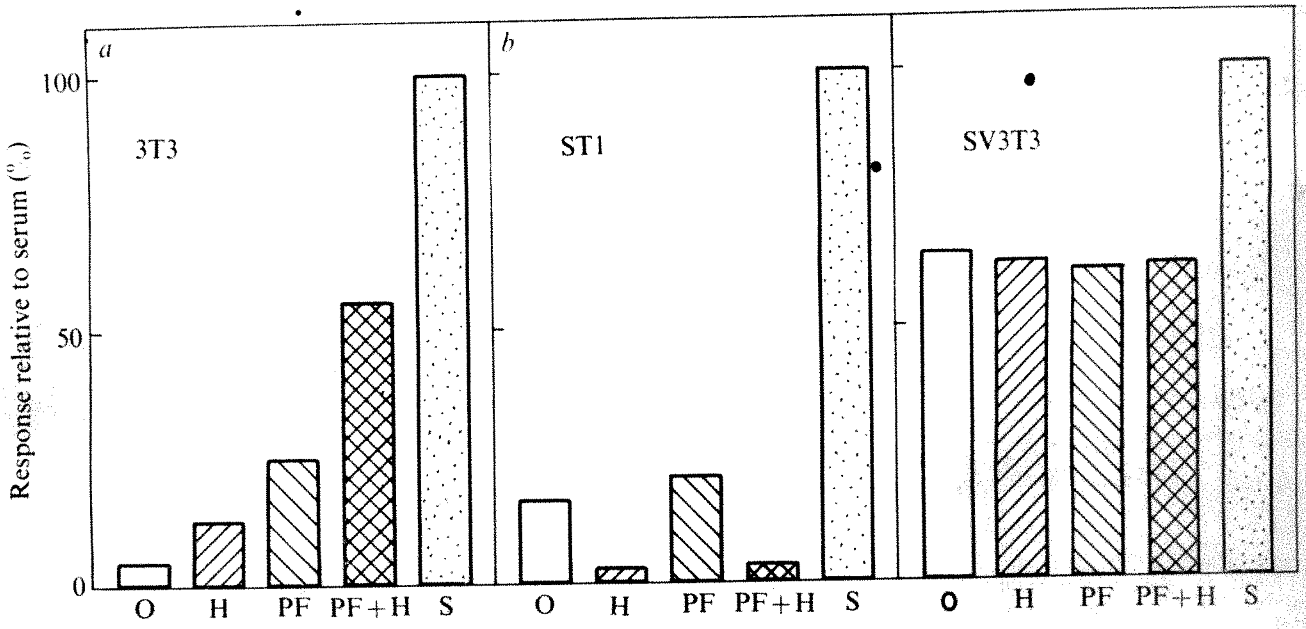

Fig. 1 Effect of hydrocortisone (H), pituitary factor (PF) and calf serum (S) on ^{3}H-thymidine uptake (0.25 μC ml^{-1}, 10^{-7} M) into DNA for three different clones of Swiss 3T3 cells (American Type Culture Collection).

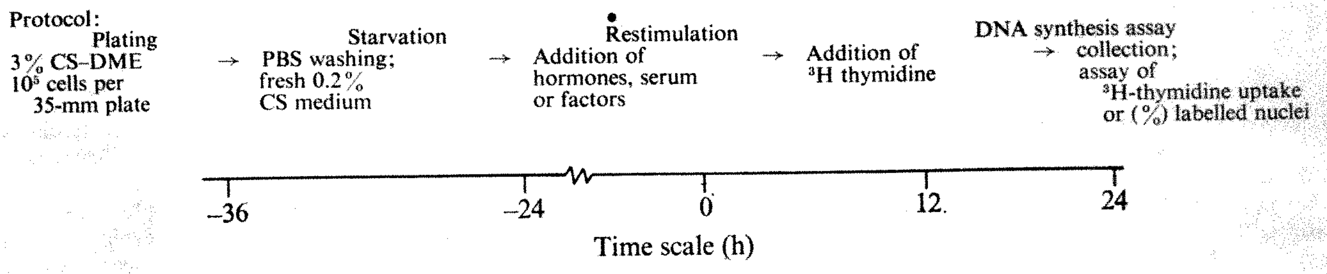

▲ Abscissa shows additions to 0.2% calf serum at $t=0$. Two plates per point. Deviation was usually 5% and never greater than 10%. ^{3}H-thymidine uptake into DNA was as described in ref. 4. 100% corresponds to 3.3×10^4 c.p.m. per plate for clone 1; 4.9×10^4 c.p.m. per plate for ST1 and 5.1×10^4 c.p.m. per plate for SV3T3. PF is a growth factor preparation from frozen bovine pituitary glands containing seven bands in polyacrylamide gel electrophoresis (ref. 19).

adhesion of this variant to the substrate is greatly affected by both the removal of serum and the addition of cyclic AMP.

We sought new cell types by cloning mutagenised and non-mutagenised 3T3 populations; routinely confluent monolayers cultures were inspected for foci of piled-up variants. Other selection procedures have also been developed which will be reported elsewhere. In one particular case, repeated plating in low serum of non-mutagenised culture containing foci yielded a population enriched with variant cells which was then cloned and recloned. Since the variant clones obtained were all identical, one was chosen and called ST1 and the others were discarded.

Figure 1 represents the typical response of clones isolated from the parental 3T3 line, the ST1 variant and SV40-transformed 3T3 (SV3T3).

As can be seen from Table 1 and Fig. 1*b*, ST1 cells have: (1) diminished density inhibition of growth—they pile up and grow in methocel; (2) serum dependence; (3) half as many chromosomes as the parental line. Also their synthesis of DNA is not dependent on pituitary factor but is inhibited by hydrocortisone. In addition, insulin (at physiological or high doses) and a somatomedin-enriched serum factor have no effect on DNA synthesis but factor(s) contaminating commercial crystalline bovine serum albumin cause stimulation (results not shown).

The hydrocortisone inhibition of growth has the following very interesting features: (1) it is specific for glucocorticoids (sex steroids have no effect); (2) glucocorticoids are effective at physiological doses; maximal effect is obtained with 20 ng ml^{-1} dexamethasone or 50 ng ml^{-1} hydrocortisone; (3) the glucocorticoid growth inhibition depends on serum

Table 1 Properties of 3T3, ST1 and SV 3T3 cells

Cell line	Saturation density (cells cm^{-2})		Doubling time (h)		Growth in methocel	No. of chromosomes per cell
	10% CS	1% CS	10% CS	1% CS		
3T3	0.4×10^5	0.9×10^4	18	90	—*	80±2.5
ST1	4.1×10^5	2.5×10^4	14.5	38	+†	40±1
SV 3T3	4.5×10^5	$2\text{-}3\times10^4$	13	13	+	75.6±4.8

Saturation density and doubling time were determined using the same batch of calf serum. Cells were plated in methocel according to ref. 20. Karyotype analysis was done according to ref. 21. At least 10 metaphase plates were counted per cell line; figures are the mean ± s.e.m.

*No visible colonies after one month of culture; eventually presence of microcolonies of up to eight cells; plating density from 10^6 to 10^3 cells per plate; efficiency of plating: zero.

†Visible (2–4 mm) colonies counted 21 d after plating; efficiency of plating in different experiments: 1 to 3%.

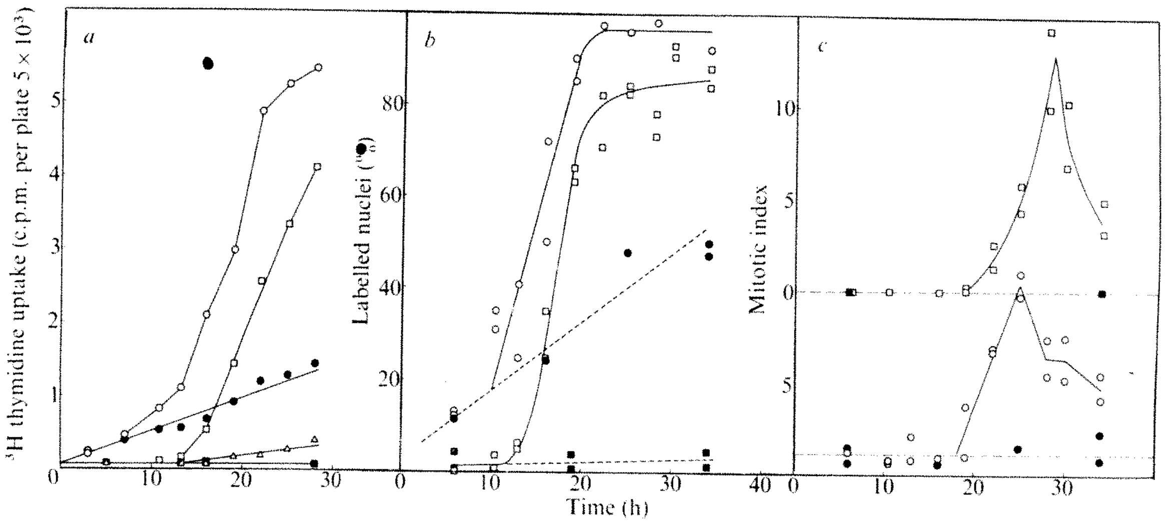

Fig. 2 Kinetics of restimulation with serum for ST1 cells treated with glucocorticoid and untreated. Cells were plated in 3% calf serum; 24 h later the medium was changed to 0.2% calf serum plus or minus hydrocortisone (300 ng ml^{-1}). After 24 h incubation in low serum, calf serum (5%) was added to restimulate cells. Plates treated with hydrocortisone were washed with PBS and received fresh 0.2% calf serum medium before serum addition. ^{3}H-thymidine (0.25 μCi ml^{-1}, 5×10^{-7} M) was added to all plates at the same time as serum. Plates were harvested at different time intervals after serum addition and assayed for: *a*, ^{3}H-thymidine uptake into DNA; *b*, percentage of labelled nuclei; *c*, mitotic index. ○, Plus serum, not treated with hydrocortisone; ●, no serum added, not treated; □, treated with hydrocortisone, steroid washed away, plus serum; ■, treated with hydrocortisone, steroid washed away, no serum added; △, treated with hydrocortisone, no serum added, steroid not washed away. Percentage of labelled nuclei determined by autoradiography using Kodak AR10 stripping film. Mitotic index determined in fixed and stained plates. Two plates per point for *a* (deviation never greater than 10%) one plate per point for *b* and *c* (at least 500 cells counted per plate in *b* and at least 1,000 cells per plate in *c*).

concentration: at 0.2% serum inhibition is 100% whereas at 5% serum it is 40%; (4) inhibition is completely reversible and glucocorticoid has no effect on cell viability: plating efficiency is the same (50–55%) in the presence or absence of hydrocortisone; (5) the inhibition, measured by 1-h ^{3}H-thymidine pulses, increases progressively with time after glucocorticoid addition, attaining its maximal level after 15–18 h of glucocorticoid addition; (6) glucocorticoids had no detectable effect on ongoing DNA synthesis or the ability of cells to undergo mitosis (data not shown); (7) 100% of the cells from an exponentially growing culture are found in a "resting" state 15–20 h after serum step-down in the presence of hydrocortisone; these "resting" cells are fully responsive on serum restimulation (Fig. 2).

The results of kinetic experiments, shown in Fig. 2, in which ^{3}H-thymidine labelling and mitotic index were followed, indicate that: (1) serum step-down causes accumulation of cells at the beginning of G_1 or at G_0, though in the absence of hydrocortisone residual DNA synthesis and growth remain; (2) from the kinetics of the stimulated DNA synthesis one can make estimates of the length of G_1 (Table 2): in the presence of hydrocortisone G_1 was longer by 4.0 h (^{3}H-thymidine uptake) or 3.8 h (labelled nuclei) than in its absence; (3) the increment in mitotic index was delayed by 3.8 h (Table 2) in cells treated with hydrocortisone, indicating that hormone-treated and untreated cells traverse S and G_2 at the same rate.

In conclusion, it seems clear to us that glucocorticoids at physiological doses inhibit growth of ST1 cells without compromising their viability or interfering with biochemical processes of S, G_2 or mitotic phase of the life cycle. This inhibitory effect seems to be directly connected with the mechanism which regulates the transition between "resting" and "proliferative" states of the cell.

Resting "normal" 3T3 cells when restimulated by serum step-up or PF addition enter the S phase, after identical G_1. Addition of hydrocortisone to PF further increases the stimulation, accelerating the entry of cells into S, but without interfering with G_1 length (M.C.S.A. and H.A.A., unpublished). This accelerating effect is due to an increase in the probability of cells exiting in the resting state. On the other hand the glucocorticoid seems to cause a resetting of the growth control mechanisms of ST1 cells, leading to a strict "resting" state with serum step-down and a larger G_1 upon restimulation by serum step-up. We feel that our approach to the growth regulation of 3T3 cells and its variants might yield new information about the mechanisms of cell growth control.

It has long been recognised that glucocorticoids inhibit the growth of fibroblasts *in vivo* and *in vitro*[13], but the mechanisms of this effect are still unknown. In culture this glucocorticoid-inhibiting effect has been studied using L cells, a line of tumorigenic mouse fibroblasts[14–17] and has also been observed with normal chick embryo cells[18]. It

Table 2 Estimates of G_1 and T (G_1+S+G_2) on restimulation of ST1 cells with serum

Kinetics of	G_1^{+H}	G_1^{-H}	(G_1^{+H}—G_1^{-H})	T^{+H}	T^{-H}	(T^{+H}—T^{-H})
^{3}H-thymidine uptake into DNA	1) 14.5 2) 14.5	1) 10.4 2) 10.6	1) 4.1 2) 3.9	—	—	—
Nucleus labelling	2) 13.9	2) 10.1	2) 3.8	—	—	—
Mitotic index	—	—	—	2) 21.8	2) 18.0	2) 3.8

G_1^{+H} and G_1^{-H} are the length of G_1 (in hours) for cells treated with hydrocortisone and untreated, respectively. T^{+H} and T^{-H} are the period of time equivalent to G_1+S+G_2 for treated and untreated cells, respectively. G_1 was estimated by taking the best-fitting straight lines from kinetic curves like the ones shown in Fig. 2*a* and *b* in the interval 0 to 22 h for non-stimulated and 11 and 22 h for stimulated cultures. The abscissa corresponding to the intercept of these two lines was taken as G_1 (or the length of time a cell takes to leave the resting state and initiate DNA synthesis or enter the S phase, see refs 5, 6 and 7) Estimates of T were obtained in a similar manner using mitotic index curves like the ones shown in Fig. 2*c*. 1 and 2 correspond to estimates obtained from two completely independent experiments.

Recent scientific and technical books

Mathematics

BERTSEKAS, Dimitri P. Dynamic Programming and Stochastic Control. (Mathematics in Science and Engineering, Vol. 125.) Pp.xv + 397. ISBN-0-12-093250-4. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) $22.50; £15.95.

CESARI, Lamberto, **KANNAN**, Rangachary, and **SCHUUR**, Jerry D. (edited by). Nonlinear Functional Analysis and Differential Equations. (Proceedings of the Michigan State University Conference.) (Lecture Notes in Pure and Applied Mathematics, Vol. 19.) Pp.xii + 352. ISBN-0-8247-6452-8. (New York and Basel: Marcel Dekker, Inc., 1976.) SFrs. 98.

CHILLINGWORTH, D. R. K. Differential Topology with a View to Applications. (Research Notes in Mathematics, 9.) Pp.291. ISBN-0-273-00283-X. (London, San Francisco and Melbourne: Pitman Publishing, 1976.) £8.50; $17.

HOPKIN, David, and **MOSS**, Barbara. Automata. (Macmillan Computer Science Series.) Pp.vi + 170. ISBN-0-333-15398-7. (London and Basingstoke: The Macmillan Press, Ltd., 1976.) £8.95 net. hard cover; £3.95 paper cover.

METROPOLIS, N., **ORSZAG**, S., and **ROTA**, G. C. (edited by). Surveys in Applied Mathematics. (Proceedings of the First Los Alamos Symposium on Mathematics in the Natural Sciences.) Pp.xv + 297. ISBN-0-12-492150-7. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) $14; £9.95.

PITTIE, H. V. Characteristic Classes of Foliations. (Research Notes in Mathematics, 10.) Pp.107. (London, San Francisco and Melbourne: Pitman Publishing, 1976.) £4.40; $8.75.

RODIN, Ervin Y. (edited by). Computers and Mathematics, with Applications (In Memory of Cornelius Lanczos.) Pp.ix + 257-425. ISBN-0-08-020521-6. (Oxford and New York: Pergamon Press, 1976.) £10; $20.

Astronomy

BURGER, J. J., **PEDERSEN**, A., and **BATTRICK**, B. (edited by). Atmospheric Physics from Spacelab.(Proceedings of the 11th Eslab Symposium organized by the Space Science Department of the European Space Agency, held at Frascati, Italy, 11-14 May 1976.) (Astrophysics and Space Science Library, Vol. 61.) Pp.xx + 408. ISBN-90-277-0768-5. (Dordrecht and Boston, Mass.: D. Reidel Publishing Company, 1976.) Dfl.105; $39.50.

HAUCK, B., and **KEENAN**, P. C. (edited by). Abundance Effects in Classification. (Proceedings of the International Astronomical Union Symposium, No. 72, held in Lausanne—Dorigny, Switzerland, July 8–11, 1975.) Pp.xxviii + 264. ISBN-90-277-0674-3. (Dordrecht and Boston Mass.: D. Reidel Publishing Company, 1976.) Cloth Dfl. 85, $31.50 Paper Dfl.69, $22.50.

HECKMANN, Otto. Sterne—Kosmos—Weltmodelle. (Erlebte Astronomie.) Pp.353. ISBN-3-492-02228-6. (München und Zürich: R. Piper und Co., Verlag, 1976.) DM 36.

KOZAI, Y. (edited by). The Stability of the Solar System and of Small Stellar Systems. (Symposia of the International Astronomical Union, No. 62, held at Warsaw, Poland, September 5–8, 1973.) Pp.313. ISBN-90-277-0458-9. (Dordrech and Boston, Mass.: D. Reidel Publishing Company, 1974.) Cloth Dfl.95, $38; Paper Dfl.70, $28.

MEABURN, John. Detection and Spectrometry of Faint Light. (Astrophysics and Space Science Library, Vol. 56.) Pp.ix + 270. ISBN-90-277-0678-6. (Dordrecht and Boston, Mass.: D. Reidel Publishing Company, 1976.) Dfl.90; $34.

Physics

BUSCH, Georg, and **SCHADE**, Horst. Lectures on Solid State Physics. Translated by Ferdinand Cap. Translation editor: D. ter Haar. Pp.xv + 538. ISBN-0-08-016894-9. (Oxford and New York: Pergamon Press, 1976.) £17.50; $35.

DAVIES, E. B. Quantum Theory of Open Systems. Pp.ix + 167. ISBN-0-12-206150-0. (London and New York: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) £7.50; $16.50.

LINDMAN, Björn, and **FORSEN**, Sture. Chlorine, Bromine and Iodine NMR: Physico-Chemical and Biological Applications. Pp. xiv + 368. ISBN-3-540-07725-1. (Berlin and New York: Springer-Verlag, 1976.) DM 96, $39.40.

MARCH, N. H., and **TOSI**, M. P. Atomic Dynamics in Liquids. Pp.vii + 330. ISBN-0-333-11278-4. (London and Basingstoke: The Macmillan Press, Ltd., 1976.) £25.

MORGAN, B. L., **AIREY**, R. W., and **McMULLAN**, D. (edited by). Photo-Electronic Image Devices. (Proceedings of the Sixth Symposium held at Imperial College, London, September 9–13, 1974.) (Advances in Electronics and Electron Physics, Vol. 40B.) Pp.xviii + 519-1074. ISBN-0-12-014554-5. (London and New York: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) no.

NOUJAIM, A. A., **EDISS**, C., and **WEIBE**, L. I. (edited by). Liquid Scintillation: Science and Technology. (Proceedings of the International Conference held at the Banff Centre in Alberta, Canada, on June 14–17, 1976.) Pp.xiv + 352. ISBN-0-12-522350-1. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) $17.50; £12.40.

RAO, K. Narahari (edited by). Molecular Spectroscopy: Modern Research, Vol. 2. Pp.xiv + 279. ISBN-0-12-580642-6 (v.2). (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) $29.50; £20.95.

RIDLEY, B. K. Time, Space and Things. Pp.169. ISBN-0-14-055-113-1. (Harmondsworth, Middx.: Penguin Books, Ltd., 1976.) £1.75; $2.95.

TANNER, B. K. X-ray Diffraction Topography. (International Series in the Science of the Solid State, Vol. 10.) Pp.xiii + 174. ISBN-0-08-019692-6. (Oxford and New York: Pergamon Press, 1976.) £6.25; $12.50.

THOMPSON, J. C. Electronic in Liquid Ammonia. (Monographs on the Physics and Chemistry of Materials.) Pp.xii + 297. ISBN-0-19-851343-7. (Oxford: Clarendon Press; London: Oxford University Press, 1976.) £14.50 net.

WEDLER, Gerd. Chemisorption: an Experimental Approach. Translated by Derek F. Klemperer. Pp.vi + 250. ISBN-0-408-10611-5. (London and Boston, Mass. Butterworths, 1976.) £12.

Chemistry

ABEL, E. W., and **STONE**, F. G. A. (senior reporters). Organometallic Chemistry, Vol. 5. (A Review of the Literature Published during 1975. A Specialist Periodical Report.) Pp.xviii + 520. ISBN-0-85186-541-0. (London: The Chemical Society, 1976. Obtainable from The Chemical Society, Blackhorse Road, Letchworth, Herts; American Chemical Society, 1155 Sixteenth Street, N. W., Washington, DC.) £29; $58.

AHMED, F. R., **HUML**, K., and **SEDLACEK**, B. (edited by). Crystallographic Computing Techniques. (Proceedings of an International Summer School organized by the Commission on Crystallographic Computing of the International Union of Crystallography, and held in Prague, Czechoslovakia, 28 July to 5 August 1975.) Pp.502. ISBN-87-16-02132-0. (Copenhagen: Munksgaard, 1976.) Dkr.336.

ALPER, Howard (edited by). Transition Metal Organometallics in Organic Synthesis, Vol. 1. (Organic Chemistry: a Series of Monographs, Vol. 33.) Pp.ix + 258. ISBN-0-12-053101-1. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) $26.50; £18.80.

ANDERSON, Robert B., and **DAWSON**, Pater T. (edited by). Experimental Methods in Catalytic Research. Vol. 2: Preparation and Examination of Practical Catalysts. (Physical Chemistry: a Series of Monographs, Vol. 15-2.) Pp.xiv + 283. ISBN-0-12-058660-6 (v.2). (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) $26.50; £18.80.

ANGUS, S., *et al.* (edited by). International Thermydynamic Tables of the Fluid State (Carbon Dioxide). (International Union of Pure and Applied Chemistry: Division of Physical Chemistry. Commission on Thermodynamics and Thermochemistry: Thermodynamics Tables Project.) Pp.xxviii + 385. ISBN-0-08-020924-6. (Oxford and New York: Pergamon Press, 1976.) £25; $50.

BAULCH, D. L., **DRYSDALE**, D. D., **DUXBURY**, J., and **GRANT**, S. J. Evaluated Kinetic Data for High Temperature Reactions. Vol. 3: Homogeneous Gas Phase Reactions of the O_2-O_3 System, the CO-O_2-H_2 System, and of Sulphur-Containing Species. Pp.xiii + 583. ISBN-0-408-70787-9. (London and Boston, Mass.: Butterworths, 1976.) £2[illegible].50.

BERNASCONI, Claude F. Relaxation Kinetics. Pp.xi + 288. ISBN-0-12-092950-3. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) $29.50; £20.95.

BRAUN, T., and **BUJDOSO**, E. (edited by). Nuclear Methods in Physical Chemistry. (Proceedings of the 8th Radiochemical Conference, Marjanske Lazne, Czechoslovakia, April 27-May 2, 1975. Reprinted from the *Journal of Radioanalytical Chemistry*.) Pp.601. ISBN-963-05-0542-8. (Budapest: Akademiai Kiado, 1976.) £28.50.

BROWN, Glenn H. (edited by). Advances in Liquid Crystals, Vol. 2. Pp.xi + 308. ISBN-0-12-025005-0. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) $30; £18.30.

BUTLER, George B., **O'DRISCOLL**, Kenneth F., and **SHEN**, Mitchel (edited by). Reviews in Macromolecular Chemistry, Vol. 14B. Pp.xvi + 316. ISBN-0557-6458. (New York and Basel: Marcel Dekker, Inc., 1976.) $32.50.

FREIDMAN, Arnold M. (edited by). Actinides in the Environment. (A Symposium sponsored by the Division of Nuclear Chemistry and Technology at the Centennial Meeting of the American Chemical Society, New York, N.Y., April 9, 1976, ACS Symposium Series, No. 35.) Pp.ix + 107. (Washington, DC: American Chemical Society, 1976.) $14.25.

GIDDINGS, J. Calvin, **GRUSHKA**, Eli, **CAZES**, Jack, and **BROWN**, Phyllis R. (edited by). Advances in Chromatography, Vol. 14. Pp.xiii + 459. ISBN-0-8247-6436-6. (New York and Basel: Marcel Dekker, Inc., 1976.) SFr.114.

GREENWOOD, N. N. (senior reporter). Spectroscopic Properties of Inorganic and Organometallic Compounds, Vol. 9. (A Review of the Literature Published during 1975. A Specialist Periodical Report.) Pp.xii + 544. ISBN-0-85186-083-4. (London: The Chemical Society, 1976. Obtainable from The Chemical Society, Blackhorse Road, Letchworth, Herts; American Chemical Society, 1155 Sixteenth Street, N.W., Washington, DC.) £28; $57.

HANZLIK, Robert P. Inorganic Aspects of Biological and Organic Chemistry. Pp.xvii + 402. ISBN-0-12-324050-6. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) $37; £26.25.

HUDLICKY, Milos. Chemistry of Organic Fluorine Compounds. Second Revised edition. Pp.xiv + 903. ISBN-85312-008-0. (Chichester: Ellis Horwood, Ltd., 1976. Distributed by Halsted Press, a Division of John Wiley and Sons, New York, London, Sydney and Toronto.) £35.50; $67.45.

KEVAN, Larry, and **KISPERT**, Lowell D. Electron Spin Double Resonance Spectroscopy. Pp.vii + 427. ISBN-0-471-47340-5. (New York and London: Wiley-Interscience, John Wiley and Sons, 1976.) £18; $30.70.

Biological sciences

CHUN, Carl. The Cephalopoda. Part 1: Oegopsida. Part 2: Myopsida, Octopoda. Text: Pp.x + 436. ISBN-0-7065-1259-6. Atlas: 95 plates. ISBN-0-7065-1260-X. (Scientific Results of the German Deepsea Expedition on Board the Steamship "Valdivia", 1898-1899, Vol. 18.) Translated from the German, (Jerusalem: Israel Program for Scientific Translations; Chichester: John Wiley and Sons, Ltd., 1975.) £95.70; $175.

CLOUDSLEY-THOMPSON, J. L. Insects and History. (The World Naturalist.) Pp.242. ISBN-0-297-77128-0. (London: Weidenfeld and Nicolson, 1976.) £8.50.

CURTIS-PRIOR, P. B. Prostaglandins: An Introduction to their Biochemistry, Physiology and Pharmacology. Pp.xi + 158. ISBN-0-7204-0588-2. (Amsterdam, New York and Oxford: North-Holland Publishing Company, 1976.) Dfl. 42; $16.25.

CUSHING, Jr., Colbert E., *et al.* (edited by). Radioecology and Energy Resources. (Proceedings of the Fourth National Symposium on Radioecology, May 12-14, 1975, Oregon State University, Corvallis, Oregon.) (The Ecological Society of America—Special Publication No. 1.) Pp.xx + 401. (Stroudsburg, Pennyslvania: Dowden, Hutchinson and Ross, Inc., 1976. Distributed by Halsted Press, a Division of John Wiley and Sons, Inc., New York and London.) £18; $30.

DAVIS, Bernard D., and **FLAHERTY**, Patricia (edited by). Human Diversity: Its Causes and Social Significance. (The Proceedings of a Series of Seminars sponsored by the Committee on Human Diversity of the American Academy of Arts and Sciences, 1973/1974.) Pp.xiv + 248. ISBN-0-88410-047-2. (Cambridge, Mass.: Ballinger Publishing Company, a Subsidiary of J. B. Lippincott Company, 1976.)

DAWES, Ian W., and **SUTHERLAND**, Ian W. Microbial Physiology. (Basic Microbiology, Vol. 4.) Pp.v + 183. ISBN-0-632-00278-6. (Oxford and London: Blackwell Scientific Publications, 1976.) £4.25.

EDWARDS, Peter. Illustrated Guide to the Seaweeds and Sea Grasses in the Vicinity of Port Aransas, Texas. Pp.128. ISBN-0-292-77549-0. (Austin and London: University of Texas Press, 1976.) £4.90.

EISENBERG, Henryk. Biological Macromolecules and Polyelectrolytes in Solution. (Monographs on Physical Biochemistry.) Pp.xviii + 269. ISBN-0-19-854612-2. (Oxford: Clarendon Press; London: Oxford University Press, 1976.) £16 net.

van den **ENDE**, H. Sexual Interactions in Plants: The Role of Specific Substances in Sexual Reproduction. (Experimental Botany: An International Series of Monographs, Vol. 9). Pp.186. ISBN-0-12-711250-2. (London and New York: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) £6.80; $14.75.

FENTRESS, John C. Simpler Networks and Behavior. Pp.x + 403. ISBN-0-87893-182-1. (Sunderland, Mass.: Sinauer Associates, Inc.; Reading: W. H. Freeman and Co., Ltd., 1976.) £12.10.

FERDINAND, W. The Enzyme Molecule. Pp.xvi + 289. ISBN-0-471-018228. (London and New York: John Wiley and Sons, 1976.) Cloth £9.50; $20. Paper £4.50; $10.

GOODFELLOW, M., **BROWNELL**, G. H., and **SERRANO**, J. A. (edited by). The Biology of the Nocardiae. Pp.xvii + 517. ISBN-0-12-289650-5. (London and New York: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) £15.

GRODZINSKII, D. M. Plant Biophysics. Translated from Russian. Pp.ix + 236. ISBN-0-7065-1563-3. (Jerusalem: Israel Program for Scientific Translations; Chichester: John Wiley and Sons, 1976.) £18.95; $32.

HAENSCH, Günther, and De **ANTON**, Gisela Haberkamp. Dictionary of Biology: English/German/French/Spanish. Pp.xii + 483. ISBN-0-444-99828-4. (Amsterdam, Oxford and New York: Elsevier Scientific Publishing Company, 1976.) Dfl. 160; $61.50.

HALLE, Willi. Zell- und Gewebezüchtung bei Tieren. (Bausteine der Modernen Physiologie.) Pp.171 (4 tafeln.) (Jena: Veb Gustav Fischer Verlag, 1976.) M 21.

HAWKSWORTH, David L., and **ROSE**, Francis. Lichens as Pollution Monitors. (The Institute of Biology's Studies in Biology, No. 66). Pp.60. ISBN-0-7131-2555-1. (London: Edward Arnold (Publishers), Ltd., 1976.) Boards £2.80; Paper £1.40.

HERMAN, Richard W., **GRILLNER**, Sten, **STEIN**, Paul S. G., and **STUART**, Douglas G. (edited by). Neural Control of Locomotion. (Advances in Behavioral Biology.) Pp.xiv + 822. ISBN-0-306-37918-X. (New York and London: Plenum Press, 1976.) $59.40.

HUGHES, A. M. The Mites of Stored Food and Houses. (Ministry of Agriculture, Fisheries and Food. Technical Bulletin 9.) Pp.400. ISBN-0-11-140909-1. (London: HMSO, 1976.) Second edition. £12.

IL'YUCHENOK, R. Yu. Pharmacology of Behavior and Memory. Translated by Scripta Technica, Inc. Pp. vi+216. ISBN-0-470-15116-1. (Washington and London: Hemisphere Publishing Corporation, 1976. Distributed by Halsted Press, a Division of John Wiley and Sons, Inc., New York and London.) $27.70; £16.

KLINKOWSKI, M., **MUHLE**, E., **REINMUTH**, E., und **BOCHOW**, H. (herausgegeben von). Phytopathologie udn Pflanzenschutz. Band 3: Krankheiten und Schädlinge der Gemüsepflanzen und der Obstgewächse. 2., überarbeitete und erweiterte Auflage. Pp.xv+914. (Berlin: Akademie-Verlag, 1976.) M.94.

KORN, Edward D. (edited by). Methods in Membrane Biology, Vol. 7. Pp.xx+267. ISBN-0-306-36807-2 (v.7). (New York and London: Plenum Press, 1976.) $31.20.

LAWRENCE, P. A. (edited by). Insect Development. (Symposia of the Royal Entomological Society of London, No. 8.) Pp.ix+230. ISBN-0-632-00049-X. (Oxford and London: Blackwell Scientific Publications, 1976. Published for The Royal Entomological Society.) £10.50.

LEE, D. L., and **ATKINSON**, H. J. Physiology of Nematodes. Second edition. Pp.x+215. ISBN-0-333-18600-1. (London and Basingstoke: The Macmillan Press, Ltd., 1976.) £5.95.

LUSCHER, Martin (edited by). Phase and Castle Determination in Insects: Endocrine Aspects. (Papers presented at a Symposium of the Section Physiology and Biochemistry of the XV International Congress of Entomology, Washington, D.C., 1976.) Pp.vii+130. ISBN-0-08-021256-5. (Oxford and New York: Pergamon Press, 1976.) £7.50; $15.

LYNN-CARPENTER, F. Ecology and Evolution of an Andean Hummingbird (*Oretrochilus estella*). Pp.74+10 plates. ISBN-0-520-09545-6. (Berkeley, Los Angeles and London: University of California Press, 1976.) $4.75.

would be interesting to find out whether the pattern of inhibition we describe for ST1 cells is a common response for fibroblasts. Such a suggestion is not unreasonable considering the results reported for chick cells[18] and L cells[17].

Interaction of two hormones and their effect on observed rate of initiation of DNA synthesis in 3T3 cells

THE rate of replication of mammalian cells changes in response to alterations in the external environment usually by expansion or contraction of the average time of the G_1 phase of the cell cycle; the remaining phases are relatively constant (S, G_2, M)[1–3]. Thus, when varying concentrations of serum[4] or the growth-promoting[5–7] factors are added to relatively quiescent fibroblastic cells variations in rates of cell division are mainly due to differences in rates of initiation of DNA synthesis[4,6]. Recently Brooks[8] has shown that addition of serum and adenosine to quiescent BHK fibroblasts stimulated the cells to enter S phase with first-order kinetics, although without adenosine the kinetics were more complicated. We now report that the stimulation of DNA synthesis induced by prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) can be described as an increase in a first-order rate constant for exit from the G_1 phase preceded by a lag phase of relatively fixed duration. Insulin and certain nutrients which increase the effect of $PGF_{2\alpha}$ upon DNA synthesis do so by changing the same rate constant.

Swiss mouse 3T3 fibroblastic cells[9] were allowed to grow and become quiescent either in Dulbecco's modified Eagle's medium (DEM) and 6% serum or in the same supplemented with additional nutrients (DMS) (Fig. 1). Addition of increasing concentrations of $PGF_{2\alpha}$ (0–200 ng ml^{-1}) to the cultures caused an increasing percentage of cells to synthesise DNA in 30 h (labelling index) up to a maximum, at 200 ng ml^{-1} of 12% or 23% in DEM or DMS respectively. Addition of a physiological concentration (50 ng ml^{-1}) of insulin alone induced only 4% or 5% of the 3T3 cells in DEM or DMS to synthesise DNA. However, addition of insulin markedly increased the response to all concentrations of $PGF_{2\alpha}$ in either medium up to a maximum labelling index of 24% and 43% in DEM or DMS respectively (synergistic effect) (Fig. 1).

Two concentrations of $PGF_{2\alpha}$ (30 and 300 ng ml^{-1}) with or without insulin were added to quiescent cultures and the cumulative labelling index was subsequently followed with time (Fig. 2). The same results were plotted as the logarithm of the percentage of unlabelled cells against time[8]. Since most of the quiescent cells (95%) were in G_1[10] the gradient of the curves in Fig. 3 gave the first order rate constant at which G_1 cells were entering the S phase at a given time. Few cells became radioactively labelled in the first 15–16 h (lag phase). The duration of the lag phase was independent of the concentration of $PGF_{2\alpha}$ with or without insulin in DEM or DMS, and in accordance with previous results for varying serum[4] or FGF[6] concentrations. At the end of the lag phase however, the rate at which cells entered S increased abruptly and within 2 h the rate constant reached a steady value (Fig. 3). Straight lines

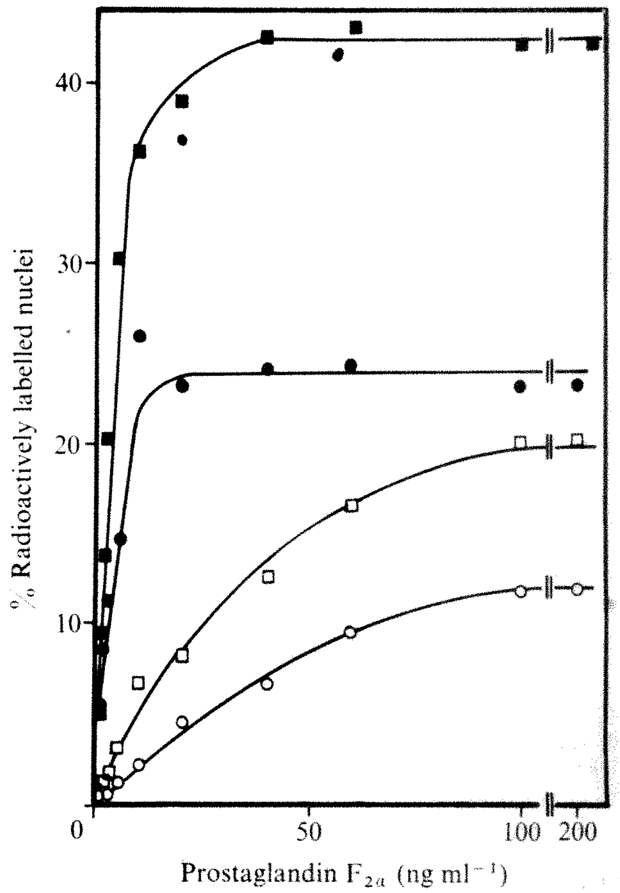

Fig. 1 Effect of different concentrations of $PGF_{2\alpha}$ on the percentage of cells synthesising DNA in 30 h. Increasing concentrations of $PGF_{2\alpha}$ were added to quiescent 3T3 cells in Dulbecco's modified Eagles medium (DEM) without (○—○) and with (●—●) 50 ng ml^{-1} insulin or to quiescent cells in DEM supplement with low molecular weight nutrients (DMS) without (□—□) and with (■—■) insulin. Swiss mouse 3T3-4 fibroblasts[9] were maintained in DEM containing 100 units ml^{-1} penicillin, 100 ng ml^{-1} streptomycin and 10% foetal calf serum. Subconfluent cultures were grown in 90 mm Nunc Petri dishes at 37 °C under a pressure of 10% CO_2 and were routinely checked for any contamination by mycoplasma[7]. Cells were plated at 10^5 per 33 mm dish in 2 ml of DEM and 6% foetal calf serum, or in DEM and 6% serum supplemented with 0.03 μM biotin, 0.05 μM vitamin B_{12}, 140 μM aspartic acid, 0.3 mM glutamic acid, 50 μM glutathione, 60 μM hypoxanthine. All additional nutrients were required to obtain the maximum stimulation of DNA synthesis by $PGF_{2\alpha}$ and insulin in 3T3 cells. All additions were made at the same time and then 3 μCi ml^{-1} methyl-^{3}H-thymidine was added at 1 μM and the cells were left for 30 h. Cultures were then processed for autoradiography as previously described[6,7], and the percentage of cells with radioactively labelled nuclei was recorded. In parallel experiments cells were radioactively labelled with 3 μCi ml^{-1} ^{3}H-thymidine at 3 μM for the same time and the radioactivity incorporated into DNA[6,7] was determined for no additions (1,500 c.p.m.); 200 ng ml^{-1} $PGF_{2\alpha}$ (26,500 c.p.m.); $PGF_{2\alpha}$ and 50 ng ml^{-1} insulin (87,300 c.p.m.) in DEM; or no additions (1,800 c.p.m.); $PGF_{2\alpha}$ (70,000 c.p.m.); $PGF_{2\alpha}$ and insulin (144,000 c.p.m.) in DMS.

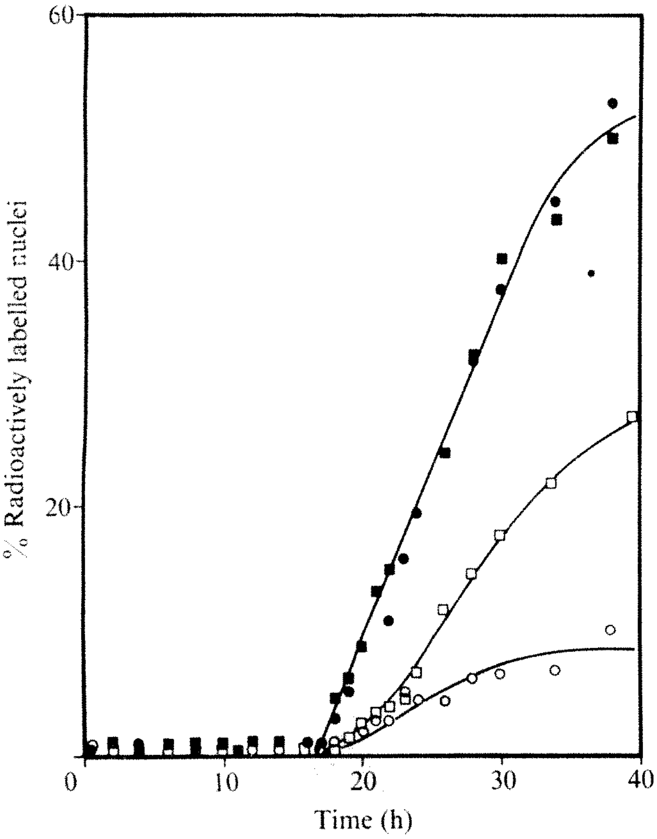
fitted the data well indicating an underlying first-order reaction or event defined by an apparent rate constant k. The goodness of fit of regression lines to the data of Fig. 3*a* and *b* was estimated by calculating coefficients of determination r^2. These ranged from 0.93 to 0.98 where $r^2 = 1$ implies a perfect fit. PGF$_{2\alpha}$ at a concentration of 30 ng ml^{-1} in DMS gave $k = 6.0 \pm 0.5 \times 10^{-3}$ h^{-1} while at 300 ng ml^{-1} $k = 1.5 \pm 0.1 \times 10^{-2}$ h^{-1}. Insulin with either 30 or 300 ng ml^{-1} of PGF$_{2\alpha}$ dramatically increased k to a value of $3.5 \pm 0.2 \times 10^{-2}$ h^{-1}. When 300 ng ml^{-1} PGF$_{2\alpha}$ and insulin were added to cells which had become quiescent in DEM or DMS the value of k was $2.2 \pm 0.1 \times 10^{-2}$ h^{-1} in DEM and $5.1 \pm 0.3 \times 10^{-2}$ h^{-1} in DMS. The corresponding value for 10% serum in DMS was approximately four times as high ($k = 0.24 \pm 0.05$ h^{-1}). Variations in absolute k values for additions of these hormones were sometimes observed for different batches of cells and serum, but the kinetics were always first order. When quiescent cells in DEM were radioactively labelled for up to 5 d (not shown) a slight but constant gradient was observed ($k = 6.4 \pm 0.5 \times 10^{-4}$ h^{-1}), presumably due to a slow rate of cell division (R. Shields and J. A. Smith, personal communication). Thus, there was probably a similar low rate of initiation of DNA synthesis during the lag phase (Fig. 3). Time-lapse cinematography of cultures indicated that cell death and detachment were occurring and this probably balanced the slow rate of cell division (R. Shields, unpublished results). When PGF$_{2\alpha}$ and insulin were not added together, but insulin was added 9 h later, the kinetics of entry into S were still first order and the rate constants were similar (Fig. 3*c*). However, when insulin was added at the end of the lag phase,

Fig. 2 Changes in the labelling index with time after addition of PGF$_{2\alpha}$ and insulin. The following additions were made: PGF$_{2\alpha}$, 30 ng ml^{-1} (○—○); PGF$_{2\alpha}$, 30 ng ml^{-1} + insulin, 50 ng ml^{-1} (●—●); PGF$_{2\alpha}$, 300 ng ml^{-1} (□—□); and PGF$_{2\alpha}$, 300 ng ml^{-1} + insulin, 50 ng ml^{-1} (■—■). The cells were grown in DMS and 6% foetal calf serum and allowed to become quiescent (Fig. 1). After additions the cultures were exposed to ^{3}H-thymidine from 0 until the indicated times. Pairs of cultures were then processed for autoradiography and the total fraction of cells synthesising DNA in that time period (labelling index) was recorded.



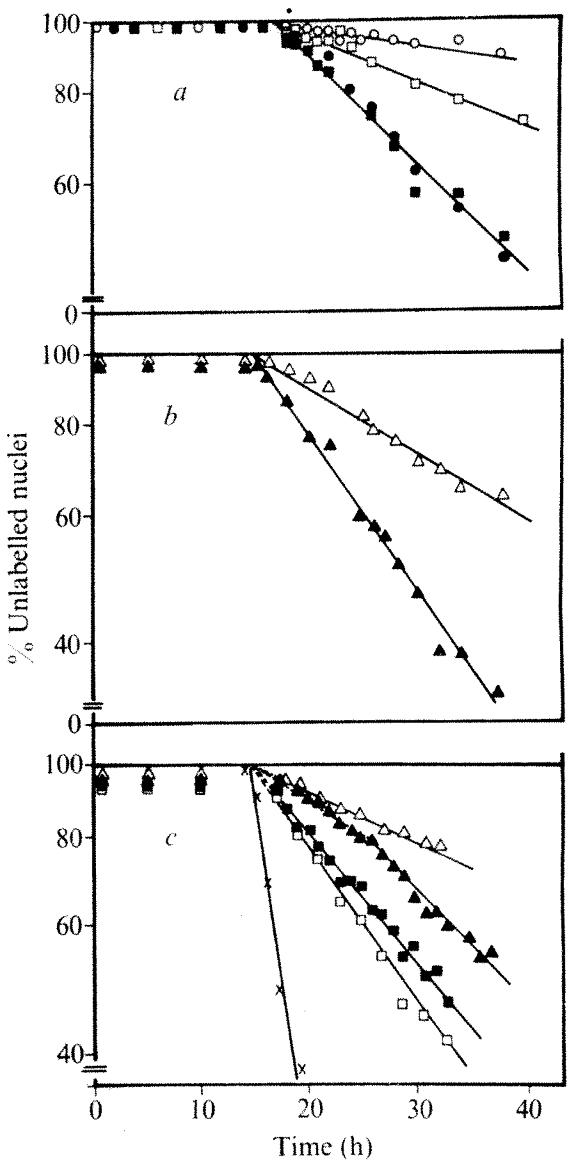


Fig. 3 *a*, Fraction of cells remaining in G$_1$ after synchronous addition of PGF$_{2\alpha}$ and insulin. The results in Fig. 2 were plotted as the logarithm (base 10) of the percentage of cells remaining in G$_1$ (percentage of non-labelled cells) $\log_{10}y$ against time (t) in hours (see below). The symbols were as follows: PGF$_{2\alpha}$, 30 ng ml^{-1} (○—○); PGF$_{2\alpha}$, 30 ng ml^{-1} + insulin, 50 ng ml^{-1} (●—●); PGF$_{2\alpha}$, 300 ng ml^{-1} (□—□); and PGF$_{2\alpha}$, 300 ng ml^{-1} + insulin, 50 ng ml^{-1} (■—■). Regression lines given by $\log_{10}y = a - bt$ were subsequently calculated for times greater than 15 h. The constants (a, b), with standard errors, were for PGF$_{2\alpha}$, 30 ng ml^{-1}; PGF$_{2\alpha}$, 30 ng ml^{-1} + insulin; PGF$_{2\alpha}$, 300 ng ml^{-1}; PGF$_{2\alpha}$ 300 ng ml^{-1} + insulin: (2.029 ± 0.004, 0.0026 ± 0.0002); (2.268 ± 0.017, 0.0154 ± 0.0007); (2.121 ± 0.013, 0.0066 ± 0.0005); (2.248 ± 0.017, 0.0148 ± 0.0007). Testing the goodness of fit yielded values of coefficients of determination (r^2) of 0.93, 0.98, 0.96 and 0.98 respectively. *b*, Fraction of cells remaining in G$_1$ in DEM and DMS after addition of PGF$_{2\alpha}$ and insulin. PGF$_{2\alpha}$, 300 ng ml^{-1} and insulin, 50 ng ml^{-1} were added to quiescent cultures grown in DEM (△—△) or DMS (▲—▲) and 6% serum. Cultures were processed as described in Fig. 2 and plotted as above. The constants (a, b), with standard errors, for the regression lines $\log_{10}y = a - bt$, were for DEM and DMS: (2.150 ± 0.015, 0.0096 ± 0.0006) and (2.332 ± 0.037, 0.0221 ± 0.0014) while $r^2 = 0.96$ and 0.97 respectively. *c*, Fraction of cells remaining in G$_1$ after non-synchronous additions of PGF$_{2\alpha}$ and insulin. PGF$_{2\alpha}$, 300 ng ml^{-1} was added to quiescent cultures grown in DMS and 6% serum. Insulin (50 ng ml^{-1}) was added at various times afterwards, as follows: no insulin (—△—△—); insulin at 17 h (—▲—▲—); insulin at 9 h (—■—■—); insulin at start with PGF$_{2\alpha}$, (—□—□—). Controls with fresh 10% serum added at the start, (—×—×—). Cultures were processed and the results plotted as above. The values for the first-order rate constants k for addition of PGF$_{2\alpha}$ with no insulin; with insulin after 17 h; with insulin after 9 h; and with insulin at the start were: 1.6 ± 0.3; 3.3 ± 0.7; 3.9 ± 0.5; and $4.7 \pm 0.8 \times 10^{-2}$ h^{-1} respectively. For 10% serum from the start $k = 0.24 \pm 0.05$ h^{-1}.

Table 1 Stimulation of rate of 2-deoxyglucose uptake, rate of cellular protein synthesis and increase in rate constant (*k*)

	2-deoxyglucose* (%)		Protein synthesis† (%) 5 h		Rate constant (*k*) for entry into S‡ (%)
Additions	1 h	5 h	Methionine	All amino acids	
None	100	100	100±4	100±9	100
Insulin	312	372	124±8	107±6	310
$PGF_{2\alpha}$	110	565	127±3	120±4	740
$PGF_{2\alpha}$+insulin	340	1,890	206±11	198±4	1,740
Serum	350	3,758	228±8	210±4	—

3T3 cultures were grown and allowed to become quiescent in DEM as in Fig. 1. Then 300 ng ml^{-1} of $PGF_{2\alpha}$, 50 ng ml^{-1} insulin, 10% foetal calf serum were added as indicated. After 45 min or 4 h 45 min, 2-deoxyglucose uptake was measured[19]. The cell monolayers were washed three times with prewarmed serum-free medium without glucose and then incubated for 15 min in the medium with hormones or serum. The cells were then exposed to 3 μCi ml^{-1} of 2-deoxyglucose at 50 μM for 15 min. Uptake into the fraction soluble in 5% trichloroacetic acid was linear for this time[19].

*Results expressed relative to the incorporation for no additions (320 c.p.m. per min per mg protein). Protein synthetic rates were determined by exposing the cultures to either 10 μCi ml^{-1} ^{35}S-methionine or 0.5 μCi ml^{-1} ^{14}C total amino acids in the normal medium from 2 h until 5 h after the additions and then removing samples every 30 min up to 6 h after adding the isotope. Cell monolayers were washed twice with isotonic saline, dissolved in 2.0 ml of 0.5 M NaOH and divided into two equal fractions. Total protein content was determined in one fraction[20], while the second fraction was incubated 1 h at 37 °C to hydrolyse the aminoacyl tRNAs. This was then precipitated with trichloroacetic acid and analysed for radioactivity[21]. The incorporation of radioactivity into the TCA-soluble pool was constant at 3 and 6 h and independent of hormonal additions, and the incorporation of radioactivity into protein per mg cell protein was linear with time for the 6-h interval[21].

†Results expressed as a percentage of the value for no additions (^{35}S-methionine, 100% = 53,500 c.p.m. per h per mg protein; ^{14}C total amino acids 100% = 7,300 c.p.m. per h per mg protein). Results ± standard errors are the means of the rates of incorporation measured over 6 h in duplicate experiments.

‡The rate constant (*k*) for cellular entry into S was calculated from the radioactive labelling index at 30 h assuming *k* to be constant and is expressed as a percentage of the value for no additions (100% = 0.10% of cells entering S h^{-1}. No value of *k* was calculated for serum addition since the rate of entry into S does not follow first-order kinetics under these conditions[8], but the labelling index at 30 h was 88%.

the rate constant gradually increased. After 9 or 10 h the rate constant was nearly the same as that for simultaneous additions. This suggested that when insulin was added near the completion of the $PGF_{2\alpha}$-induced lag phase changes in the rate constant for entry into S could be produced without appreciable delay.

$PGF_{2\alpha}$ and insulin separately increased protein synthetic rates about 1.2-fold, but when added together they increased the rates by a maximum of about 2-fold after 5 h (Table 1). Synergistic effects of $PGF_{2\alpha}$ and insulin were observed in the protein synthesis-dependent increase in 2-deoxyglucose uptake (Table 1) which also started after 2–6 h. The latter increases were much larger (19-fold) than those in total protein synthesis and closely reflected the increased rate constants for entry into S (ref. 12) (Table 1). No synergistic effects, however, were observed in the initial protein synthesis-independent increases in 2-deoxyglucose (Table 1) rubidium[13] or phosphate[13] uptakes.

Our results are compatible with the two models of the cell cycle proposed by Smith and Martin[14] and by Pardee[15]. In the former model cells enter an indeterminate state (A state) in G_1. From this they proceed to the determinate phase (B phase) of the cell cycle (S, G_2, M and remainder of G_1) at random with a constant probability (*P*). This predicts first-order kinetics of initiation of DNA synthesis in constant conditions. The growth stimulation of quiescent cells is then a switching of the cell population from one A state to another of higher *P*. In the second model the major growth regulatory point in a cell exists as a single restriction point (R point) in G_1 for critical nutrients and growth-stimulatory agents. Readdition of these components to deprived cells results in a constant lag phase prior to DNA synthesis.

A single, rate-limiting step or event is strongly suggested by the first-order kinetics of cellular entry into S phase. This step may occur close to the onset of DNA synthesis[16]. As shown above, $PGF_{2\alpha}$ and insulin interact synergistically upon the rate of the cells' entry into the S phase, and thus presumably upon that step. Interaction also occurs in some of their effects involving protein synthesis although not always at their first presumed site of action in the plasma membrane[17,18]. It is thus possible that the interaction upon DNA synthesis may, like that upon 2-deoxyglucose uptake, depend on synergy upon synthesis of protein(s). This is not inconsistent with the ability of insulin when added later than $PGF_{2\alpha}$ to affect the initiation of DNA synthesis within a few hours. As the duration of the lag phase appears independent of serum[4,6,8,11], or hormonal concentrations[6] the events determining this duration may be partly different from those by which hormonal concentrations determine the rate of initiation of DNA synthesis.

L. J. de A. is a Special Fellow of the Leukemia Society of America, Inc. We thank Dr R. Dulbecco for support and encouragement, Dr J. Smith for discussions, Mrs Helga Durbin for technical assistance and Drs J. Smith, J. Robinson, and L. Martin for criticism of the manuscript.

Cyclic AMP regulation of mitogen-induced interferon production and mitogen suppression of immune response

In a recent review, adenosine 3′,5′-cyclic monophosphate (cyclic AMP) was proposed to have an inhibitory effect on the immunological and inflammatory functions of leukocytes[1]. Guanosine 3′,5′-cyclic monophosphate (cyclic GMP) has been shown to reverse the inhibitory effect of cyclic AMP in the *in vitro* immune response, and it has been proposed that the ratio of cyclic AMP to cylcic GMP determines whether an immune response will be enhanced or suppressed[2]. Cyclic AMP has recently been shown to inhibit the production of several soluble lymphocyte mediators (lymphokines) under antigen or mitogen stimulation[3–5]. T lymphocyte mitogens are potent inhibitors of the *in vitro* immune response as a result of stimulation of suppressor cell activity[6–8]. They are also potent stimulators of the synthesis of a unique type of interferon by T lymphocytes[9–11]. Evidence suggesting that this interferon may be the mediator of some forms of suppressor T cell activity has been presented[11]. I examine in this report the ability of exogenous cyclic AMP, and agents that increase the endogenous level of cyclic AMP, to block both the production of mitogen-type interferon and the development of the suppressor state in an *in vitro* murine antibody system. The data show that cyclic AMP blocks both aforementioned T cell functions, and are consistent with the hypothesis that interferon may be the mediator of some forms of suppressor cell activity[11].

Figure 1 presents data showing dibutyryl cyclic AMP inhibition of the production of interferon in C57B1/6 mouse spleen cell cultures that were stimulated by the two T cell mitogens concanavalin A (con A)[12] and staphylococcal enterotoxin A (SEA)[8]. Dibutyryl cyclic AMP, 2×10^{-5} M, inhibited con A stimulation of interferon production by 96%, while 1×10^{-4} M inhibited SEA stimulation of interferon production by 85%. When the same concentrations of dibutyryl cyclic AMP were added to the supernatant fluids of mouse spleen cell cultures after complete interferon production, no inhibition of antiviral activity of the interferon was observed, so it is concluded that dibutyryl cyclic AMP blocked the production of interferon, and not the established activity of produced interferon.

Table 1 presents data on dibutyryl cyclic AMP blockade of mitogen-induced suppression of the *in vitro* plaque-forming cell response to sheep red blood cells (SRBC). SEA

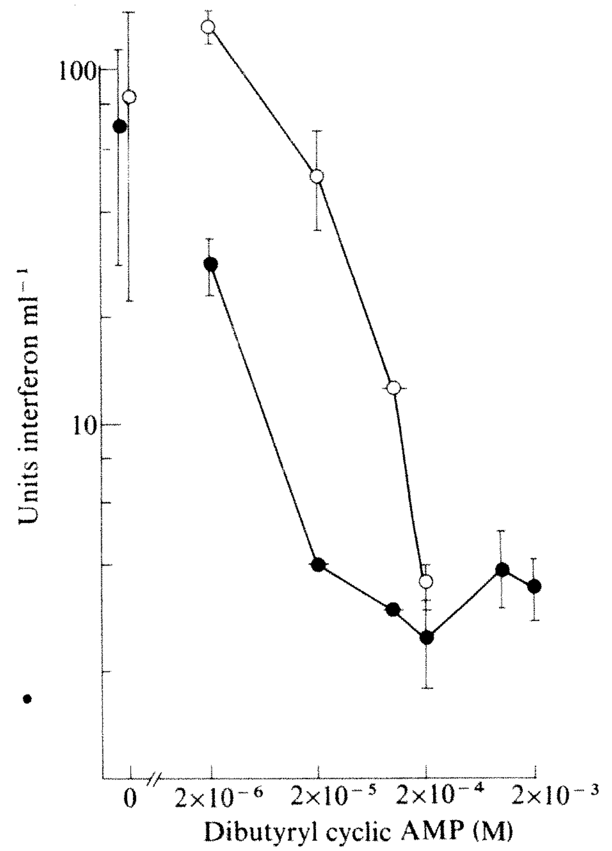

Fig. 1 Dibutyryl cyclic AMP inhibition of the production of interferon in concanavalin A (con A, ○) and staphylococcal enterotoxin A (SEA, ●) stimulated C57B1/6 female (8 week old) mouse spleen cell cultures. Cultures consisted of 1.5×10^7 spleen cells per ml and 2 μg and 1 μg con A and SEA, respectively. The con A and SEA are the same mitogens used previously[11]. Dibutyryl cyclic AMP was obtained from Calbiochem, San Diego, California. Dibutyryl cyclic AMP and mitogens were added to cultures in modified minimal essential media (MEM) (100-μl volumes) at the same time and the cells were incubated for 48 h as previously described[11]. Supernatant fluids were obtained by centrifugation of the collected cultures at 1,000 r.p.m. in a RC-3 Sorvall centrifuge at 7 °C. Fluids were assayed on the day of collection for mitogen-induced interferon activity in mouse L cells by a slight modification of the method of inhibition of cytopathic effect of vesicular stomatitis virus (100 $TCID_{50}$ per challenge dose)[13]. Data are plotted as units of interferon ml^{-1} ± s.d. for duplicate samples.

Table 1 Effect of dibutyryl cyclic AMP on mitogen-induced suppression of the *in vitro* PFC response to SRBC

Mitogen	Mitogen concentration (μg ml^{-1})	Dibutyryl cyclic AMP (1.4×10^{-4} M)	PFC per culture ± s.d.	PFC per 10^6 viable cells ± s.d.
SEA	0.25	—	350 ± 71	64 ± 8
SEA	0.50	—	550 ± 71	101 ± 11
SEA	0.25	+	13,150 ± 2051	5,080 ± 820
SEA	0.50	+	13,500 ± 1414	5,508 ± 1406
—	—	+	9,650 ± 2616	4,148 ± 296
—	—	—	18,350 ± 4596	5,206 ± 3626
Con A	1.0	—	25 ± 35	7 ± 9
Con A	2.0	—	100 ± 71	16 ± 11
Con A	1.0	+	1,900 ± 566	1,577 ± 505
Con A	2.0	+	1,750 ± 424	1,456 ± 307
—	—	+	9,775 ± 1308	3,146 ± 537
—	—	—	15,325 ± 5409	2,571 ± 691

Dissociated normal female (8 week old) C57B1/6 mouse spleen cells were cultured for *in vitro* anti-SRBC plaque-forming cell (PFC) response exactly as described by Mishell and Dutton[14]. Cultures consisted of 1 ml of 1.5×10^7 spleen cells ml^{-1} and 3×10^6 SRBC. Dibutyryl cyclic AMP was added to cultures 1 h before mitogen and SRBC addition. Dibutyryl cyclic AMP and mitogens were diluted in modified MEM, and added to cultures in 100 μl volumes. All PFC responses were determined at day 5. Cell viabilities were determined by trypan-blue dye exclusion. Direct PFC assays were carried out on microscope slides as previously described[15]. Results are expressed as the average of duplicate cultures ± s.d.

Table 2 Effect of agents that increase endogenous cyclic AMP levels on SEA-induced suppression of the *in vitro* PFC response to SRBC

Agent (μg ml^{-1})	SEA (0.5 μg ml^{-1})	PFC per culture ±s.d.	PFC per 10^6 viable cells ±s.d.
—	+	1,625±247	431±135
Cholera toxin (0.1)	+	9,600±1061	2,984±596
Cholera toxin (0.1)	—	7,225±1096	4,791±165
—	—	13,150	4,326
—	+	500±71	91±42
IMX (12.5)	+	5,300±424	3,973±477
IMX (12.5)	—	3,500±1556	1,366±571
—	—	9,850±283	2,294±1238

Cholera toxin and IMX (3-isobutyl-1-methyl xanthine) were added to *in vitro* plaque-forming cell (PFC) cultures under the same conditions as described in Table 1. IMX was obtained from Aldrich Chemical Company, Milwaukee, Wisconsin. Results are expressed as the average of duplicate cultures ±s.d., except where only one culture was assayed.

at 0.25 and 0.50 μg ml^{-1} inhibited the plaque-forming cell response by >90% when compared to cultures receiving either SRBC alone or dibutyryl cyclic AMP along with the SRBC. Protection of the plaque-forming cell response was essentially complete when dibutyryl cyclic AMP (1.4×10^{-4} M) was added to cultures along with SEA. The protection of the anti-SRBC plaque-forming cell response was significant when expressed either as plaque-forming cells per culture or plaque-forming cells per 10^6 viable cells. Dibutyryl cyclic AMP protection of the plaque-forming cell responses from con A suppression was also observed. Con A at 1.0 and 2.0 μg ml^{-1} inhibited the plaque-forming cell response by >90% when compared to the controls. Blockade of suppression was more dramatic when the plaque-forming cell response was expressed in terms of viable cells recovered, since the presence of con A and dibutyryl cyclic AMP in the same culture resulted in relatively fewer viable cells recovered as compared to the presence of the two agents in separate cultures. The control containing dibutyryl cyclic AMP and SRBC produced fewer plaque-forming cells per culture than that containing only SRBC, but the responses were essentially the same when expressed as plaque-forming cells per 10^6 viable cells. The reduction in the plaque-forming cell responses due to the dibutyryl cyclic AMP alone, then, can be attributed to the smaller number of viable cells recovered after incubation. This latter observation is in agreement with a recent report[16] that showed that cyclic AMP did not inhibit the *in vitro* immune response at concentrations used here. Repeated experiments showed the same pattern of dibutyryl cyclic AMP blockade of mitogen-induced suppressor activity. Further, dose–response studies with various concentrations of dibutyryl cyclic AMP showed that the concentrations (1×10^{-4} to 2×10^{-4} M) of the cyclic ribonucleotide that blocked the development of suppressor activity correlated with those concentrations that blocked the production of interferon in spleen cultures (Fig. 1) stimulated by the T-cell mitogens. Dibutyryl cyclic GMP, at the same concentrations, had no effect on either mitogen stimulation of interferon production or mitogen-induced suppression of the *in vitro* plaque-forming cell response.

Cholera toxin raises the endogenous level of cyclic AMP by stimulating adenyl cyclase activity[17]. The methyl xanthine 3-isobutyl-1-methyl xanthine (IMX) raises the endogenous cyclic AMP level by inhibiting phosphodiesterase activity[18]. Both agents blocked SEA suppression of the *in vitro* anti-SRBC plaque-forming cell response in a manner similar to that observed for dibutyryl cyclic AMP (Table 2). Further, they blocked SEA stimulation of interferon production in mouse spleen cell cultures at concentrations that blocked SEA suppressor activity. Theophylline, also a phosphodiesterase inhibitor, had an effect similar to that of IMX on the suppressor activity of SEA.

Dibutyryl cyclic GMP (10^{-3} and 5×10^{-4} M) did not affect the ability of dibutyryl cyclic AMP (1.4×10^{-4} M) to block the suppression of the plaque-forming cell response by SEA; nor was the effect of dibutyryl cyclic AMP on mitogen stimulation of interferon affected by dibutyryl cyclic GMP. This is further evidence that the phenomena reported here are due to cyclic AMP, and are not influenced by cyclic GMP is this system.

The data are evidence that cyclic AMP, at the concentrations ($2.0\times10^{-5}-2\times10^{-4}$ M) employed here, selectively blocks mitogen induced suppressor cell activity, while not inhibiting T helper cell function, since SRBC is a thymus-dependent antigen[14]. Further, the biological function was associated with inhibition of mitogen induction of interferon in the spleen cell cultures. This suggests that mitogen-induced interferon is associated with mitogen-induced suppressor cell activity, and that the interferon may possibly be a mediator of such activity[11]. In related studies, it has been shown that high concentrations (10^{-3} M) of dibutyryl cyclic AMP can inhibit the yield of interferon from phytohaemagglutinin-stimulated human peripheral leukocytes[5] and from virus- or polyribonucleotide-stimulated mouse L cell cultures[19]. The data presented here show a logical and integrative relationship between cyclic AMP, lymphokine (interferon) activity, suppressor cell activity, and regulation of the immune response.

We thank Phyllis Myers and Kley Hughes for technical asistance. Highly purified cholera toxin was kindly supplied by Dr Johnny W. Peterson.

Variant strain of rabbits lacking immunoglobulin κ polypeptide chain

The antibody molecule consists of heavy and light polypeptide chains[1]. The light chains are shared by all immunoglobulin classes and they can be divided into two types, κ and λ. The great majority (up to 95%) of rabbit IgG molecules possess the κ type. This polypeptide chain, like many others, shows genetic polymorphism called allotypy[2–5]; the b locus of the rabbit determines allotypes which exist in four allelic forms, namely b4, 5, 6 and 9. They are inherited in Mendelian fashion as codominant genes[3,4] and they have been correlated with amino acid sequences in the constant part of the κ chain, although some authors could associate amino acid differences in the variable part of this chain with certain b locus allotypes[4–7]. The allotypes of the λ chain are determined by an independent c locus (specificities c7 and 21). They do not show Mendelian segregation, at least in our rabbit colony, although they do in certain strains[1,8].

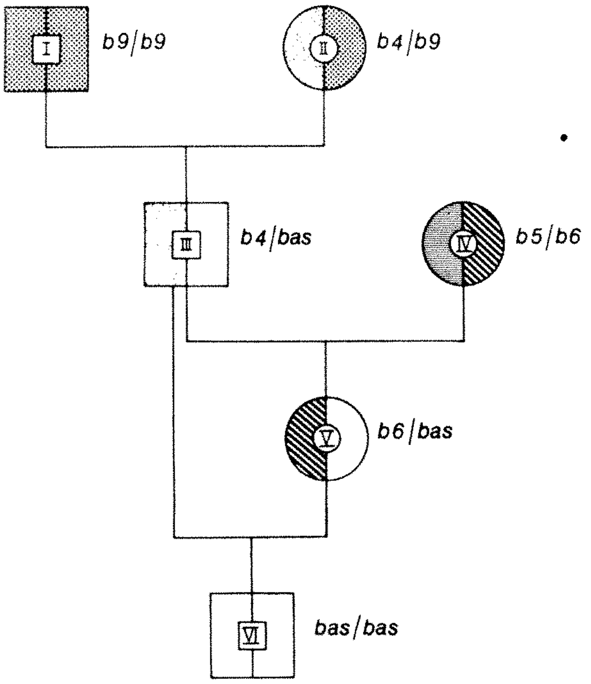
We have established a new rabbit strain, named BASILEA, which derived from a mutant. Individuals of this strain lack the κ polypeptide chain which is replaced almost entirely by the λ type. The mutation, called *bas*, is an allelic form of the b locus.

A male rabbit (Fig. 1, no. III) was born in our colony. He lacked the b9 allotypic marker of the homozygous father (Fig. 1, no. I) who sired 35 normal offspring, all expressing this allotype. Rabbit no. III could have been classified as an illegitimate child. However, parents and offspring of this family have been checked for more than 20 genetic markers of immunoglobulins and all but one (b9) were in agreement with established patterns of inheritance. In addition, rabbit no. III has been tested with 15 anti-b9 antisera in double diffusion with negative results, although the method (see Fig. 2) is able to pick up antigen concentration as low as 10–1 μg ml^{-1}.

Subsequently, rabbit no. III has been outbred and then back-crossed, and the progeny brother-sister mated. Table 1 summarises data from this breeding, and shows that this b allotype negative marker behaves like an allele at the b locus (for example, rabbit no. VI in Fig. 1).

Extensive immunisation[3] with IgG bas of rabbits of various genetic make up did not result in production of anti-allotypic antibodies against b bas as a whole. (It did, however, reveal another allotypic system which is the subject of a separate paper). On the other hand, homozygous *bas/bas* rabbits were capable of making good antibodies against the b4, 5, 6 and 9

Fig. 1 Pedigree of the original bas family.



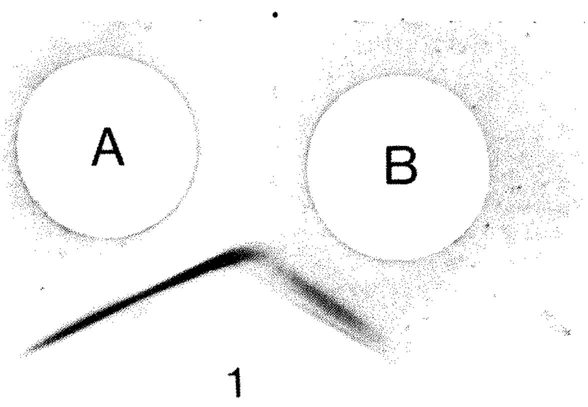


Fig. 2 Double diffusion pattern in agarose showing identity between anti-b9 produced in a standard rabbit (A) and in a bas mutant (B); (1) pool of IgG b9 (1 mg ml^{-1}). Double diffusion tests were performed in a gel composed of 1.5% agarose (A45, Indubiose, L'industrie Biologique Française, S.A.) and 2% polyethylenglycol 6000 in PBS (phosphate buffered saline) at *p*H 7.2. The plates, 1 mm thick, with 5 mm distance between the wells, were developed at 4 °C for 24–48 h. They have been examined unstained or stained with amino black or Coomasie blue. This method allowed us to see the precipitation lines at the antigen concentration as low as 10^{-1} μg ml^{-1}.

Fig. 3 Direct binding of anti-light chain allotypic and anti-isotypic antisera to a pool of Fab bas fragment. Radioimmunoassay: Fab fragments of rabbit IgG have been prepared by papain digestion in a routine fashion and iodinated (^{125}I) using the chloramine T method (50 μg mCi^{-1})[9]. The tests were performed immediately after labelling. The antigen was diluted in 1% ovalbumin made in PBS to give 10,000 c.p.m. per 50 μl. This latter volume contained 8,000 c.p.m. of ^{22}NaCl as volume control. Various amounts of antiserum were mixed and incubated, 2–4 h at room temperature with this aliquot of antigen. After the incubation, 0.1 ml of 10% *Staphylococcus aureus* vaccine, strain Cowan I, has been added[10]. This strain is known to possess large amounts of a so-called protein A which binds Fc of most mammalian IgG classes. The *Staphylococcus* suspension was prepared in PBS containing 0.1% Na azide and 0.2% Nonidet P-40 detergent. This suspension was washed well to remove debris and other impurities of free protein A. After incubation the mixture was centrifuged at 5,000 r.p.m. for 15 min and about 50% of the supernatant removed, then the pellet fraction and the supernatant examined in the γ counter. Percentage binding, including volume control, was calculated according to the equation published previously[11]. We controlled the maximum binding by titrating the antiserum and *Staphylocoocus*. Non-specific binding was within the range of 3%. Tests were carried out in duplicate.

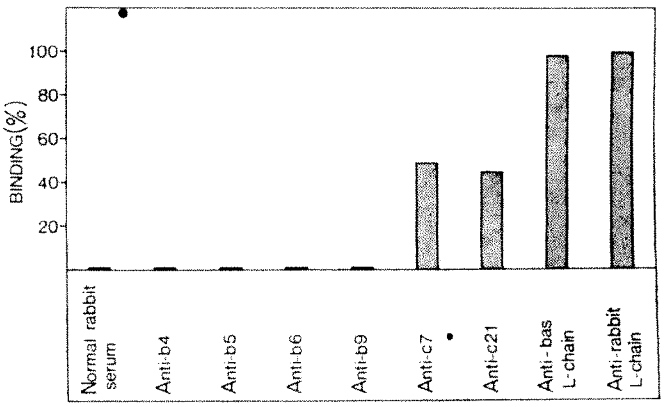

Table 1 Distribution of allotypes in the progeny of crosses involving the *bas* marker

b^i, b^j and b^k represent various alleles at the b locus. For example, b^i/b^j are heterozygous and may be b^4/b^5 or b^4/b^6 or b^5/b^6 . . . etc. Phenotypes i, j and k include also *bas* heterozygotes. The expected values, shown in brackets, are used for the χ^2 calculation.

*These values are calculated including the Yates' correction for continuity.

allotypes. It is worth noting that such an anti-b4 antiserum cross reacts strongly in double diffusion tests in gel, with b5 and b6. What is even more important, the bas rabbits can produce specific anti-b9 antiserum (see Fig. 2). This is convincing evidence that the ancestral b9 allotype was absent from the *bas* mutant.

To confirm the results obtained by double diffusion in gel that the κ chain allotypes were absent from IgG bas, direct binding of various allotypic and isotypic antisera to Fab bas was carried out. Figure 3 illustrates these results. None of the anti-b allotype antisera bound Fab bas in a detectable amount. On the contrary, anti-c7 and anti-c21 antisera, specific for λ chain allotypes, bound up to 95% of bas (50% and 45% respectively). Guinea pig anti-bas light chain and swine anti-rabbit light chain (Nordic Immunology) bound bas up to 100%. Anti-κ light chain antisera were excluded from this test as non-specific (contaminated with anti-λ antibodies).

Guinea pigs were immunised with λ light chain from rabbits suppressed for the b locus allotype[12–14], and with the bas light chain. Figure 4 illustrates that the bas chain is either identical with or very closely related to the light chain of the suppressed rabbits.

This observation has also been confirmed by the inhibition of direct binding of anti-bas light chain to Fab bas (Fig. 5). Fab fragments were used as inhibitors (light chain preparations gave similar results). The homologous Fab fragment (bas) inhibited the binding 100%, whereas the Fab of suppressed rabbits showed biphasic curves reaching also almost 100% inhibition eventually. Altogether only 50% of this light chain (as Fab) binds anti-c7 and anti-c21 antibodies, and therefore may contain determinants in a concentration different from that of the homologous Fab bas. When Fab b9, which contained 10% non-b9 (λ chain), was used as inhibitor, a pattern similar to the homologous one was observed but the curve was shifted by one order of magnitude. The b9 preparation came from rabbits closely related to the strain BASILEA. The controls with Fab b4 and b5 showed different inhibition curves, indicating much less similarity between bas and b4 or b5. This can be explained by the presence of λ chain in these preparations. Nevertheless, weak cross-reactivity between κ and λ chains cannot be ruled out. The radioimmunoassay revealed in addition that the preparations of the bas chain and of the light chain of suppressed rabbits has about 5% of either subtype of κ or subtype of λ[15].

Preliminary immunochemical data (in collaboration with Dr J-C. Jaton) show that the amino acid composition of the bas light chain resembles the λ type. As judged by similarities, the peptide maps of the light chains[16,17] fall into two groups; group I: b9, bas light chain and that of suppressed rabbits (almost entirely λ), group II: b4, b5 and b6 (all three chain preparations almost entirely of the κ type).

To see how the bas mutation influences the expression of the b locus, various Fab preparations from rabbits, homozygous or heterozygous for the b locus were tested for binding to anti-b allotype sera. The antisera used were strictly specific; none of them bound Fab bas but they reacted with 90–95% of their corresponding Fab. The same was true when Fab preparations from animals heterozygous for bas and the corresponding *b* allele were tested. Fab b4-5 from heterozygotes show the

Fig. 4 Double diffusion pattern in agarose showing identity or close similarity between anti-bas light chain (A) and anti-light chain from suppressed rabbits (B) made in guinea pig; (1) light chain from rabbits suppressed for the b-locus 1 mg ml^{-1}. The test was performed as described in Fig. 2. The precipitation was overdeveloped to see also minor components. When bas light chain was used as antigen analogous results were obtained.

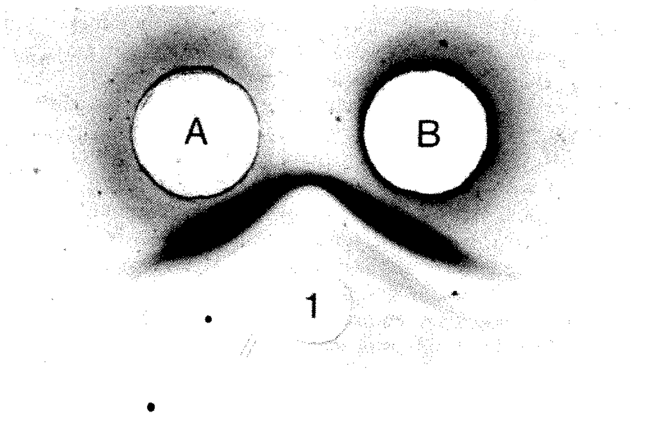

Fig. 5 Inhibition of binding of anti-bas antiserum to Fab bas by various Fab fragments. The test was performed as described in Fig. 3 but different amounts of inhibitor were added to the antigen before application of the antiserum. A serum concentration was used to get 50% binding without inhibitor. Percentage inhibition was calculated according to a published formula[11]. Each point represents the mean of quadruplicates. ●, bas; ◆, suppressed for b5; ○, b9; ◇, b5; ▲, b4.

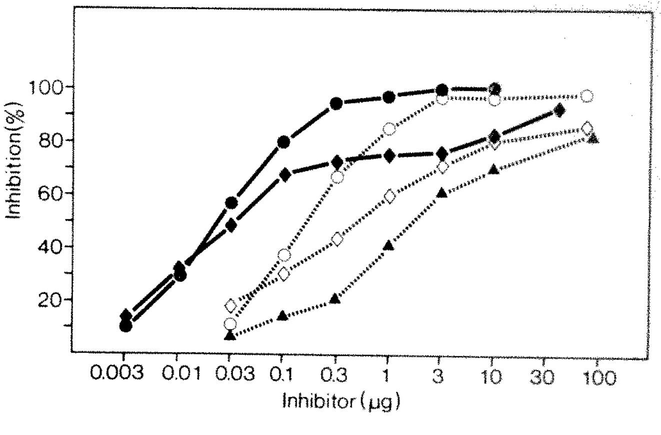

expression of both alleles as expected[4]. By analogy, with the rabbits heterozygous at the b locus and suppressed[14] for one allele only, the heterozygotes *b4/kas* and so on maintain a normal κ: λ ratio, that is, one 'κ chromosome' is enough to regulate this ratio.

Rabbits of the strain BASILEA are healthy and have normal level of IgG unlike the few cases described in man[18,19]. They produce good antibodies to rabbit allotypes and idiotypes, against sheep erythrocytes, dinitrophenol (DNP), and *Proteus*, *Pneumococcus* and *Streptococcus* vaccines. Immunisation with the group A-variant streptococcal vaccine (in collaboration with Dr D. G. Braun) gave a high proportion (8 out of 10 individuals) of restricted immune response[20] as judged by microzone electrophoresis and isoelectric focusing. The antibodies eluted from the bacterial cell wall and tested serologically proved to be of the λ type.

In conclusion, we may say that the *bas* variant of the rabbit arose by spontaneous mutation affecting the b locus of the chromosome region coding for the κ polypeptide chain or an essential part of it. Deletion seems to be the most likely mechanism, although many other explanations could be considered. The BASILEA strain resembles rabbits suppressed completely for the b locus allotypes, and it offers immense experimental opportunities.

We thank Mr John Hatton for assistance, and the following colleagues for some reagents: J. Andersson, D. G. Braun, S. Dubiski, J-C. Jaton, Katherine L. Knight, Rose G. Mage and W. J. Mandy.

Lymphocytes with T-cell markers cooperate with IgG antibodies in the lysis of human tumour cells

THYMUS-DERIVED (T) lymphocytes from animals immunised with syngeneic or allogeneic tumour cells are well known to kill specifically target cells *in vitro*[1]. The as yet unidentified antigen recognition structure on T lymphocytes is not deemed to be a conventional type of immunoglobulin. In contrast to this kind of cell-mediated cytolysis another cellular killing mechanism has been described, called antibody-dependent cell-mediated cytolysis (ADCC), in which cells bearing the Fc receptor (FcR) cooperate with humoral antibody in the cytolytic action[2,3]. The nature of the main lymphoid effector cells (K cells) involved in the latter system is still ill-defined. They are supposed not to be T lymphocytes. Recently however, Lamon *et al.* reported on mouse thymocytes which were able to lyse MSV-induced tumour cells using IgM antibodies[4]. In this report we present evidence that human lymphocytes bearing the T marker in collaboration with homologous or autologous antibodies can efficiently kill tumour cells *in vitro*.

The data were obtained with an ADCC system[5,6] consisting of cultured melanoma cells as target cells, different preparations of human peripheral blood lymphocytes as effector cells, and anti-melanoma cell antisera obtained from melanoma patients. The cytolytic activity of lymphocytes was measured by the ^{3}H-proline release test as described previously[7]. Antibodies increasing the spontaneous cell-mediated cytolysis (CMC) of melanoma cells by more than 100% were detected in 17 out of 87 patients. Immunoglobulins were isolated from patients' sera by affinity chromatography using insolubilised antibodies rendered monospecific for heavy chain determinants of either IgG, IgM or IgA. Non-adherent lymphocytes were prepared as described previously[7]. T lymphocytes defined as cells having receptors for sheep erythrocytes (SRBC), were purified by two different procedures: either by passing the cells through IgG anti-IgG Degalan^R-bead columns according to Golstein *et al.*[8] or by density gradient centrifugation as spontaneous rosettes with SRBC (E-RFC)[5]. The various lymphocyte preparations were characterised by surface markers as depicted in Table 1.

As can be seen from Fig. 1*a* the passage of lymphocytes through an IgG anti-IgG bead column resulted in a complete loss of spontaneous cytotoxicity. However, the capacity of column-filtrated cells to cooperate with anti-tumour antibodies was not affected when tested in the long term ^{3}H-proline release assay. Furthermore, these cells still responded to mitogens such as PHA and concanavalin A indicating functional integrity (Table 1). When—as a control—cells were passed through a FCS-coated Degalan column, neither the CMC- nor the ADCC-activity was reduced. These findings obtained in eight independent experiments were rather unexpected since almost no FcR-bearing cells could be detected immediately after column fractionation when tested by a sensitive radioautographic method using ^{125}I-labelled aggregated IgG (^{125}I-agg. IgG) of defined size[9] (Table 1).

Because ADCC is thought to depend on the presence of FcR-bearing cells the question arose whether Fc receptors and ADCC activity were generated *de novo* during the 40 h cocultivation with target cells. Therefore, column fractionated lymphocytes were incubated together with unlabelled tumour cells for 6, 12, and 48 h. After various periods of incubation the FcR-bearing cells were enumerated and ADCC was assessed in a short-term 6 h ^{3}H-proline release assay. As demonstrated in Table 2 the percentage of FcR-bearing cells increased with time of cocultivation, reaching approximately the pre-filtration value after 48 h. No ADCC activity could be detected immediately after the column passage, independent of the effector cell–target cell ratio used (Fig. 1*b*). However, significant ADCC reappeared after 12 to 24 h of cocultivation with either syngeneic or allogeneic melanoma cells, and increased further up to 48 h. In some experiments (for example experiment 2, Table 2) the generated ADCC activity considerably exceeded the prefiltration value. In control experiments where lymphocytes were cultured without tumour cells under otherwise identical conditions very few FcR-bearing cells could be detected up to 48 h and ADCC remained marginal when compared with that of cocultured cells. Thus, the increase of the number of FcR-bearing cells and ADCC activity during cocultivation may not be due to deblocking of FcRs occupied by IgG or complexes released from the column. This assumption is supported by additional observations (data not shown): first, when ^{125}I-labelled goat anti-human IgG or ^{125}I-labelled human IgG (at least 100 μCi per column) were used for the preparation of the IgG anti-IgG column, neither by direct counting in a gamma counter nor by radio-autography could a significant radioactivity be detected on the passed cells. Second, the proportion of FcR-bearing cells after column filtration did not increase after trypsin treatment. In addition, unspecific retention of cytotoxic effector cells on protein-coated Degalan beads was rendered unlikely, since FCS-coated control columns did not reduce the proportion of FcR-bearing cells. The difference in cell yield, however, between both columns

Table 1 Characterisation of purified lymphocytes immediately after filtration through IgG anti-IgG bead columns or FCS-coated control columns and separation of E-rosette forming cells

Results are means ± s.d. of five independent experiments, except the PHA and con A stimulation where the data of one representative experiment are given. Preparation of effector cells from human peripheral blood and determination of surface markers was performed as described previously[5,7,9]. SRBC were lysed by short (20–40 s) hypotonic treatment with distilled water. ^{3}H-thymidine incorporation in con A and PHA-stimulated cultures was determined using 1×10^6 lymphocytes, cultured in 1 ml RPMI 1640 supplemented with 10% human AB-serum for 48 h in the presence of various concentrations of PHA-P (DIFCO Laboratories) (1–10 μg ml^{-1}) and con A (Pharmacia Fine Chemicals) (0.1–25 μg ml^{-1}). After 40 h of culture 1 μCi ml^{-1} ^{3}H-thymidine was added for an additional 8 h. Results are expressed as mean c.p.m. of triplicate cultures ± s.e.

* Percentage of monocytes was estimated according to reactions for N-AS-Acetate-Esterase and Peroxidase.

† Recovery of cells from the column: 50–60%.

‡ Recovery of cells from the column: 80–85%.

** Radioactivity incorporated in unstimulated cultures 673 ± 312 c.p.m.

cannot be fully explained by retention of cells bearing detectable FcRs and/or S-Ig (Table 1).

More than 95% of the column fractionated cells proved to be E-RFCs. Since a considerable portion of the FcR-bearing lymphocytes generated *in vitro* also bound SRBC, it was assumed that these cells were derived from the original T-cell inoculum. Such double marker cells are also present in the peripheral blood as originally described by Dickler *et al.*[10] Thus lymphocytes were isolated as E-rosettes and found to contain about 3.5% of ^{125}I-agg. IgG-binding cells, most of them simultaneously binding SRBC (Table 1). These purified E-RFCs displayed ADCC activity comparable with unseparated lymphocytes in a 6 h ^{3}H-proline release assay without prior cultivation on tumour cells (Fig. 1*c*).

The antibodies which induce cytolytic effects with the subset of lymphocytes described above could be confined to the IgG class as demonstrated in Table 3. IgM or IgA fractions of the antisera tested so far were not active in ADCC.

If the binding of SRBC is considered a valid marker for human T lymphocytes, the data presented strongly suggest that a subpopulation of T lymphocytes is able to induce lysis of tumour cells with the help of IgG antibodies. So far, only peripheral T lymphocytes showed this effect, whereas thymocytes were inactive. The mechanism of the *in vitro* induction of cooperative cytotoxicity is unknown. The time kinetics suggest that activation by lymphocyte–tumour cell contact may lead to a rapid reappearance of Fc-receptor activity on the effector cells, which in turn might increase ADCC activity. In agreement with the data presented are the observations of Biberfeld and Perlmann[11] describing a considerable proportion of lymphocytes bearing T-cell marker in a cytolytic plaque assay. Receptors for the Fc-portion of either the IgG[12-15] or the IgM[4,15] molecule have been described for various T-cell subpopulations. The finding that spontaneous cytolytic activity is lost by passage of the lymphocytes through IgG-anti-IgG columns, also described by others[16], suggests that FcR- and/or S-Ig bearing cells are effector cells in spontaneous cytotoxicity. Recent findings in our laboratory (J. G. Saal *et al.*, in preparation) together with the data presented here, point to the possibility that T lymphocytes armed *in vivo* by humoral IgG

Table 2 Appearance of aggregated IgG binding and ADCC activity during cocultivation of human lymphocytes bearing T markers with allogeneic and syngeneic melanoma cells

Expt	Cultivation of purified lymphocytes	%CTL in a 6-h ADCC assay: Before column filtration	%CTL: Period of cultivation after column filtration (h) 0	12	48	% ^{125}I-agg.IgG-binding cells: Before column filtration	% ^{125}I-agg.IgG-binding cells: Period of cultivation after column filtration (h) 0	12	24	48
1	With allogeneic tumour cells	17 ± 4	0 ± 0	4 ± 1	12 ± 1	5.5	0.2	0.8	1.5	2.5

Lymphocytes from melanoma patients were depleted for Fc-receptor- and S-Ig-bearing cells by filtration through IgG anti-IgG bead columns and cultivated either alone or together with 1×10^4 syngeneic or allogeneic melanoma tumour cells in Falcon-Microtest II plates. The cells were collected at the intervals indicated and tested for either ADCC activity in a 6-h ^{3}H-proline release test (as described in legend to Table 3) or uptake of ^{125}I-agg.-IgG by radioautography. Effector cell–target cell ratio = 50:1.

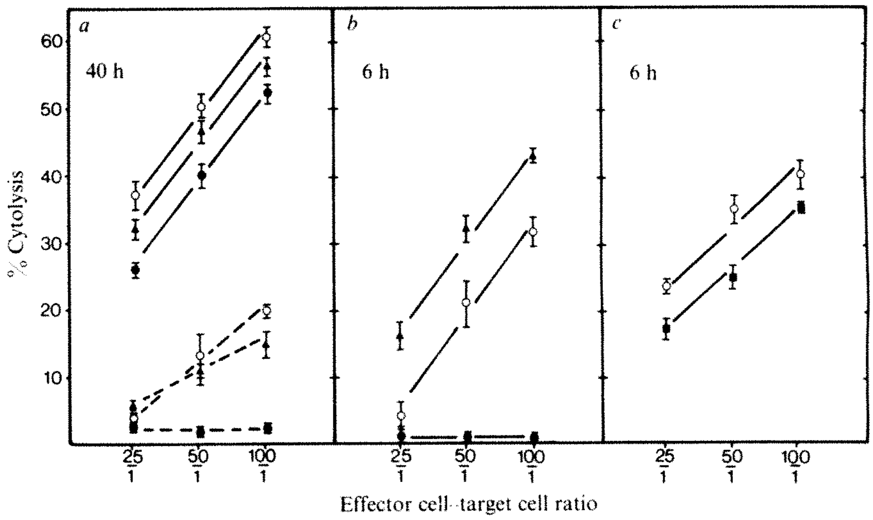

Fig. 1 Spontaneous (CMC) and antibody dependent (ADCC) cytolytic activity of different lymphocyte preparations. Open circles (○) indicate the cytolytic activity of cells before column filtration or E-rosette centrifugation (non-adherent lymphocytes). ●, Cells after passage through IgG anti-IgG columns; ▲, cells after passage through FCS-coated control columns; ■, pelleted E-RFCs. CMC is given by the dashed lines and ADCC by the solid lines. Cytolytic activities were measured either in a 6-h (expt. *b*,*c*) or a 40-h (expt. *a*) ^{3}H-proline release test. The test was performed as described in legend to Table 3. Effector cell–target cell ratios of 25/1, 50/1 and 100/1 were tested. Results are means of triplicate tests ± s.e. In the 6-h assays depicted in Fig. 1*b*, *c* no measurable CMC was detected.

Table 3 Cytolytic activity of lymphocytes before and after filtration through IgG anti-IgG bead columns: cooperative effect with antibodies directed against melanoma cell membrane

Antiserum added	Cytolysis (%) in a 40-h ^{3}H-proline release test with Non-adherent lymphocytes	Cytolysis (%) in a 40-h ^{3}H-proline release test with Lymphocytes after IgG anti-IgG column fractionation
No serum (CMC)	17±1	0±0
Whole serum	44±1	40±1
IgG fraction	39±1	39±1
IgM fraction	14±2	2±1
IgA fraction	11±3	n.t.

CMC was measured by the ^{3}H-proline release test as previously described in detail[7]. $5 \times 10^6 - 1 \times 10^7$ mel-Ei-78 tumour cells labelled 24 h with 50 μ Ci ^{3}H-proline (500–1,000 mCi mmol^{-1}) were distributed into Falcon Microtest-II plates (1×10^4 per well). 5×10^5 effector lymphocytes were added in RPMI 1640 with 10% human AB serum. ADCC was assessed by adding a human anti-melanoma antiserum to the CMC system at a final dilution of 1:6. IgM or IgA was isolated from the antiserum by affinity chromatography with sepharose-coupled antibody previously rendered monospecific for the IgG-IgM- or IgA-heavy chains.

ADCC is defined as antibody-induced cytolysis superimposed on spontaneous CMC. The antiserum without lymphocytes never showed more than 4% cytolysis (CTL). After 6–40 h of incubation at 37 °C the total content of each well was collected on glass filters by use of an automatic harvesting device. The radioactivity retained on the filter was determined in a liquid scintillation counter.

CTL was calculated by:

$$\% \text{CTL} = 100 - \frac{\text{c.p.m. test sample}}{\text{c.p.m. medium control}} \times 100$$

Results are means of triplicate tests ± s.e.
n.t., not tested.

antibodies are involved in spontaneous cytotoxicity.

Cμ4 domain of IgM has cytophilic activity for human lymphocytes

WE have isolated and identified two intact Cμ4-domain fragments from a monoclonal IgM protein. They differed only in their carbohydrate content, having the same polypeptide chain. They were separated from each other and from Fcμ monomer by molecular exclusion and affinity chromatography (insolubilised concanavalin A[1]) of mildly reduced and alkylated Fc$_5\mu$ produced by the method of Plaut and Tomasi[2]. The Cμ4 fragment containing carbohydrate was designated Cμ4(+) while the carbohydrate-poor domain was called Cμ4(−). These two fragments were identified as Cμ4-domains from their amino acid sequences, amino acid compositions, molecular weights (14,700) and antigenic characteristics. Both fragments originate from tryptic cleavage at Lys-445 of the μ chain (IgM(Ou) numbering[3]) and could not be further fragmented by extensive reduction and alkylation[4]. The domain hypothesis of Edelman *et al.*[5] proposes that each homology region of the immunoglobulins evolved to perform independent biological effector functions. Hurst *et al.*[6] have shown that fragmented Cμ4 domain will fix activated Cl(Cl) and will also activate proenzyme Cl to Cl'. Moretta *et al.*[8] have demonstrated receptors specific for IgM on human T lymphocytes, and this has been confirmed by McConnell and Hurd[9]. We now report that these receptors are specific for the Fc part of IgM (Table 1) and furthermore that the Cμ4 domain is involved in this affinity reaction in a dose-dependent manner (Fig. 1).

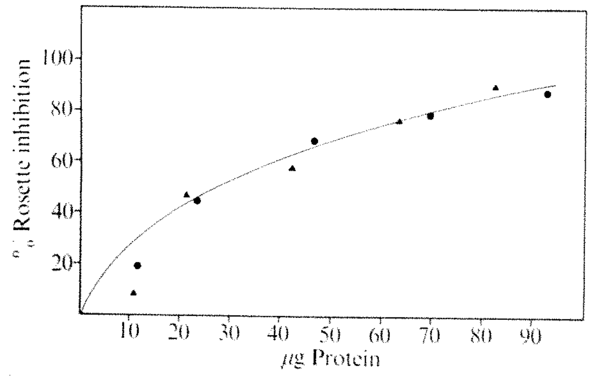

Fig. 1 Dose-dependent inhibition of EA(IgM) rosette formation by C 4(+) protein. Methods used were the same as that described in Table 1. ●, Experiment 1; ▲, experiment 2.

Several workers have concluded that the classical pathway of complement activation is mediated by the Cγ2 (ref. 13) region of IgG (Table V, ref. 14). In the case of cytophilic reactions, however, the situation is not so well defined; Cγ2, Cγ3 or intact Fc region being implicated (Table V, ref. 14). Our results show that Fcμ (that is Cμ3–Cμ4) and Cμ4 fragment inhibit EA(IgM) rosette formation to approximately the same extent, and it must therefore be deduced that the Cμ3 domain does not contribute significantly to this activity. In contrast to Fcγ, minimal non-covalent interactions occur in Fcμ (ref. 15), and as a result the protein exists mainly as a monomer in solution. This is important because both Fcμ and Cμ4 inhibit rosette formation quite efficiently (Table 1), indicating that the Fcμ receptor does not require antigen binding to or a polymeric form of IgM in order to fulfil its unknown function. Two biological functions—complement fixation[6] and cytophilic activity—have now been attributed to the Cμ4 domain of IgM.

Table 1 Inhibition of EA(IgM) rosette formation by IgM and some of its fragments

Inhibitor	Concentration (mg ml^{-1})	Inhibition of EA(IgM) rosettes (%) exp. 1	exp. 2
None	—	0	0
IgG	9.9	2.2	0
IgM	0.52	81.9	90.6
Fc5μ	0.50	97.8	96.1
Fcμ	0.52	53.6	58.6
Fabμ	4.1	0	0
Cμ4(+)	0.42	47.8	46.1
Cμ4(−)	0.70	65.2	59.4

The formation (and inhibition) of IgM-dependent rosettes (EAIgM-RF) was carried out as described by Moretta *et al.*[8] Rabbit antisera containing mainly IgM antibodies to ox erythrocytes were raised according to Mayer[10] and the fraction containing IgM was isolated by molecular exclusion chromatography on Sephadex G-200. IgG was purified by DEAE–cellulose chromatography of Cohn fraction II and IgM, $Fc_5\mu$, Fcμ and Fabμ as previously described for normal IgM[11]. The protein concentration of the inhibitors tested was determined by the Folin Ciocalteau method[12] using recrystallised bovine serum albumin as standard. Three hundred lymphocytes were counted for each test and only those cells with three or more adhering EA(IgM) were scored as rosettes.

Common antigens and male-female recognition in plants

THE question of how the female stigma of the plant recognises a pollen grain carrying a compatible male gamete from all the possibilities presented to it by air currents and visiting insects is an intriguing problem[1]. When pollen is recognised at the stigma surface, a mixture of components, including proteins and glycoproteins, are released from cavities in the pollen walls[2,3]. These components have been partially characterised[4,5] and include those essential to the recognition process[6]. The pollen wall components flow over and bind to the stigma surface which is covered by a secreted sticky coating[7]. The binding of specific recognition factors determines the success of a mating[8]. We have attempted to identify factors involved in pollen-stigma recognition, using immunochemical methods with rabbit antisera to pollen and stigma surface components. The major antigen of the stigma surface shows immunological identity and has the same molecular weight as an antigenic pollen wall component. This stigma antigen is also partially identical with components of other tissues of the same plant. Absorption experiments show that the cross-reacting antibodies can be removed from the antisera, leaving antibodies which interact only with the immunising antigen. This raises the question whether plant cells, like animal cells[9], are specified according to their family, species, organ and tissue by surface determinants.

Antisera were raised in rabbits to both stigma surface extracts and pollen wall components of *Gladiolus*

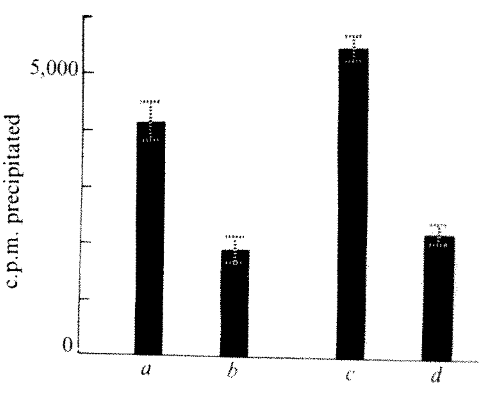

Fig. 1 Immune precipitation of ^{125}I-pollen and stigma antigens of *Gladiolus* by homologous and heterologous antisera. A double antibody precipitating system was used: to 200 μl of radio-iodinated pollen or stigma extracts (10^6 c.p.m.) were added 100 μl of a 1 : 20 dilution of rabbit antiserum. The precipitate was developed by addition of 200 μl of a 1 to 4 dilution of goat antiserum to rabbit IgG followed by incubation for 1 h at 37 °C and 15 h at 4 °C. Data given are ^{125}I-radioactivity associated with precipitates which were washed twice by centrifugation. *a*, ^{125}I-pollen + anti-pollen serum; *b*, ^{125}I-pollen + anti-stigma serum; *c*, ^{125}I-stigma + anti-stigma serum; *d*, ^{125}I-stigma + anti-pollen serum.

gandavensis cv[10]. Stigma antigens were prepared by washing receptive stigmas with 0.05 M Tris buffer, *p*H 8.4, 0.15 M NaCl and 0.001 M $CaCl_2$, and dialysing and freeze drying the material washed from the surface. Pollen antigens were allowed to diffuse from the wall cavities for 10 min in the same buffer and the filtrate was dialysed and freeze dried.

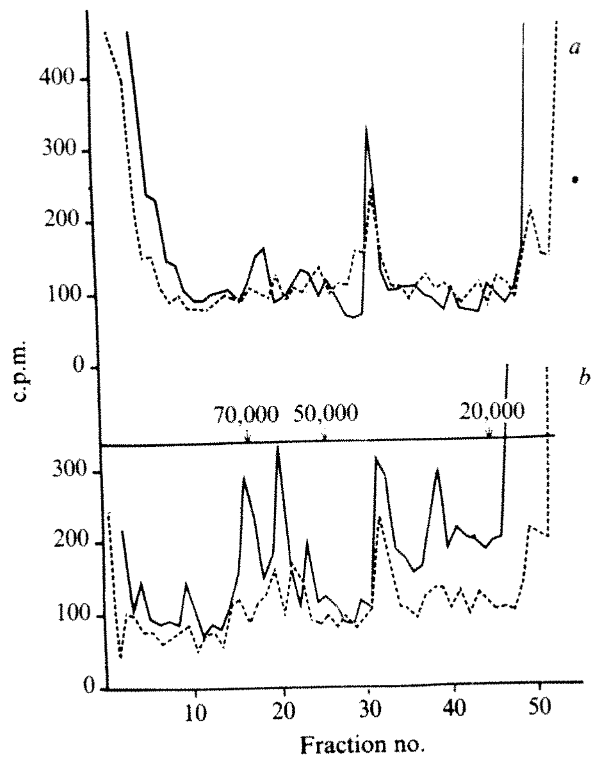
Samples of both stigma and pollen antigens were labelled with ^{125}I by the lactoperoxidase method[9] and incubated with both the homologous and heterologus antisera. The immune precipitates were collected, washed and counted. The results (Fig. 1) show specificity of precipitation in both the homologous stigma–antistigma and the pollen–antipollen systems, as well as some cross reactivity in the heterologous systems.

The washed immune precipitates were dissociated and the components were separated by sodium dodecyl sulphate (SDS) polyacrylamide gel electrophoresis. The gels were cut into 2-mm slices which were counted individually. The distribution of radioactivity is shown in Fig. 2. These patterns show a major antigen in the stigma surface preparation, molecular weight ~40,000, and this cross reacts with antisera raised to pollen from the same plant. The reciprocal experiment confirms this: pollen contains seven major antigens, of which that of molecular weight ~40,000 cross reacts with antisera raised to the stigma surface.

In gel immunodiffusion experiments (Fig. 3), antisera to stigma surfaces show two bands, one of which shows partial identity with a petal component and a pollen wall component. Of the five precipitating antigens of pollen, two are common to both corm and petal, and the slower diffusing of these is also common with the stigma. In addition, petal also contains two other components which form precipitin bands with antisera to pollen, and one of these is also present in corm.

Absorption of antisera to stigma surfaces with petal antigen removed the capacity of the serum to precipitate the petal antigen, but did not apparently affect the capacity of the serum to precipitate either the pollen or the stigma antigens. Likewise, the absorption of the antisera with pollen antigen removed the capacity of the serum to precipitate the pollen antigen, but the absorbed antisera retained the capacity to precipitate the stigma antigens. Stigma-absorbed antisera would not precipitate with either petal, pollen or stigma antigens.

Fig. 2 Analysis of ^{125}I-stigma (*a*) and pollen (*b*) antigens of *Gladiolus* on SDS polyacrylamide gels after precipitation of homologous antisera (solid line) and heterologous antisera (broken line). Immunoprecipitates were dissociated in 200 µl of Tris buffer, *p*H 6.8, containing 3% SDS and 5% β-mercaptoethanol, and run on SDS polyacrylamide gels as described by Laemli and Favre[16]. The gels were sliced and radioactivity was determined using a Packard autogamma counter.



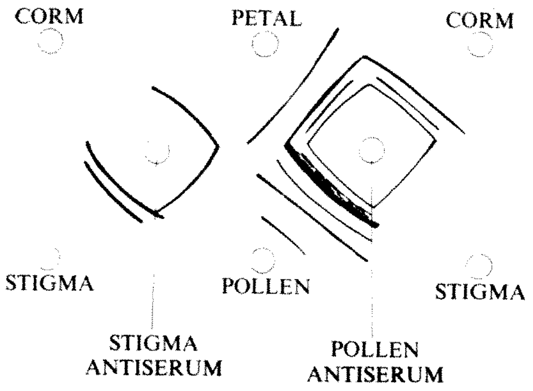


Fig. 3 Immunodiffusion of *Gladiolus* tissue antigens against antisera raised to stigma surface preparations and pollen wall components. Agar gel immunodiffusion plates were run using antigens at 10 µg ml^{-1} in 0.15 M NaCl and whole antisera. Antigens were prepared by homogenising the tissue (0.25 g fresh weight per ml of 0.05 M Tris, *p*H 8.5, 0.15 M Na Cl, 0.001M $CaCl_2$) and dialysing and freeze drying the supernatant.

One explanation for these results is that stigma surface determinants in this system are partially identical with determinants of other tissues of the same plant. It may be that variation in the degree of identity of this component in pollen and stigma controls the positive recognition in the pollen–stigma system. This conforms with suggestions[12–14] that the recognition genes in self-incompatible plants may specify identical products in stigma and pollen. Several groups of stigma surface components have been described[8], but their individual antigenicity is not known. It is, however, possible that some of the antigens are isozymes of hydrolytic enzymes common to both sites[15].

The finding that a closely related determinant is present in petals, and the observation of antigens common to pollen and other tissues of the same plant, may indicate that male-female recognition factors are part of a wider system of recognition factors involved in such basic functions as cell growth and differentiation, which are reflected in economically important problems such as scion–rootstock incompatibility in fruit trees and other horticultural crops.

Solubilisation of phospholipid membranes by human plasma high density lipoproteins

HUMAN plasma high density lipoproteins (HDL) seem to have a protective effect against the development of atherosclerosis[1,2]. Glomset proposed that unesterified cholesterol diffuses from cell membranes into the HDL particle following esterification of cholesterol in HDL by the action of plasma lecithin: cholesterol acyltransferase[3]. In tissue culture experiments, HDL[4] and complexes of its apoproteins with phospholipids[5] removed cholesterol from arterial smooth muscle cells, and the principal HDL apoprotein, apo-A1, adsorbed to and removed phospholipid from Landschutz ascites cells[6]. We show that intact HDL releases part of its apoprotein when incubated with synthetic phospholipid membranes, leading to the formation of soluble, discoidal phospholipid–apoprotein complexes. The residual apoprotein-deficient HDL particles seem to undergo fusion.

The human plasma HDL are spherical particles, 95–105 Å in diameter, consisting of a polar shell of phospholipid head groups and apoproteins surrounding a core of apolar lipids[7,8]. The protein moiety comprises about 60% apoprotein-A1 (molecular weight 28,331)[9] and 30% apoprotein-A2 (molecular weight 17,380)[10]. Studies of HDL by differential scanning calorimetry have shown that apo-A1 is released from HDL following heating to 100 °C, giving rise to a characteristic reversible thermal denaturation of lipid-free apo-A1[11,12]. This transition with midpoint temperature at 54 °C has been used to monitor release of apo-A1 from HDL (Fig. 1). By heating HDL, cooling, then reheating to progressively higher temperatures, the fraction of apo-A1 released with each increment in temperature was calculated from the enthalpy of the transition at 54° C. These experiments indicate that almost all of the apo-A1 of each HDL preparation can be released in lipid-free form between 55 and 80 °C. Between 80 and 95 °C cholesterol ester is liberated from HDL, which can be demonstrated on cooling by the appearance of reversible liquid crystalline transitions between 11 and 33 °C (Fig 1*g*), and the presence of smectic liquid crystals by polarising microscopy[13]. With each HDL preparation more than 90% of the apo-A1 was released before cholesterol ester liquid crystalline transitions could be demonstrated. Since domains of cholesterol ester as small as 1,000 molecules (as in low density lipoprotein) show liquid crystalline transitions[14], HDL partially depleted of apo-A1 must exist as a stable microemulsion containing small domains of cholesterol ester, probably fewer than 1,000 molecules.

Apo-A1, released from HDL by heating, could be isolated by preparative ultracentrifugation. HDL was heated to 70 °C for 15 min, cooled and centrifuged at d (density) 1.25 g ml^{-1}.

The infranatant contained 5–15 times more lipid-free (that is, containing less than 1% phospholipid) protein than control, unheated HDL preparations, and when examined by Sephadex G-200 chromatography and polyacrylamide gel electrophoresis, the protein consisted of >90% apo-A1. The supernatant was optically clear and by electron microscopy (EM) contained spherical particles of diameters 90–180 Å (mean ± s.e.m. = 145 ± 3.1 Å, n=90), which were significantly larger than those present in control preparations (91 ± 2.8 Å (n=100). The larger particles present in the supernatant probably arose from fusion of HDL particles secondary to the loss of amphiphilic apoprotein molecules. In experiments where HDL was heated to a series of temperatures above 55 °C, an increasing amount of pure apo-A1 was recovered in the infranatant between 60 and 85 °C, in quantities corresponding to the increasing enthalpy of the 54 °C transition in the differential scanning calorimetry experiments (Fig. 1).

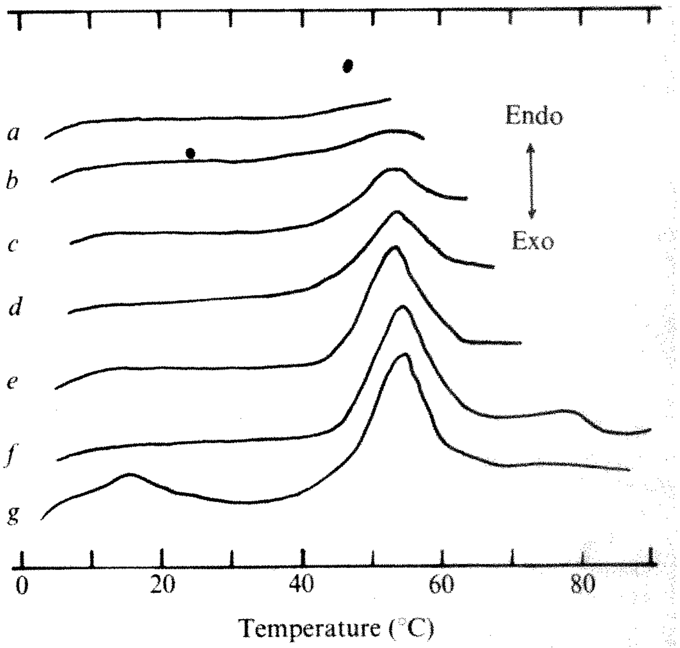

Fig. 1 Differential scanning calorimetry tracings of the thermal disruption of HDL. Human plasma HDL was isolated from the blood of normal fasting male donors by ultracentrifugal flotation between 1.063 and 1.21 g ml^{-1} as previously described[12]. The lipoprotein samples were concentrated to 10–30% solids by vacuum dialysis. Differential scanning calorimetry experiments were performed on a Perkin Elmer DSC-2B, calibrated with cyclohexane and indium. Experiments were performed in 75 λ sealed stainless steel pans at heating rates of 2.5 or 5 °C min^{-1}. HDL was heated to progressively higher temperatures with 5 °C increments on each heating run, and cooled at 10 °C min^{-1}. The heating runs to 75, 80 and 85 °C were identical to *e*. Experimental results were independent of lipoprotein concentration. In experiments where apo-Al was heated repeatedly to the same temperature, above 55 °C, there was an increase in the endotherm at 54 °C, on the second heating run (by 10–40%), the third heating run (5–10%), but not on the fourth and subsequent heating runs. Repeated heating to temperatures below 55 °C did not result in liberation of apo-Al. The low temperature transition (Fig. 1*g*) is attributed to cholesterol ester because it has the same temperature and enthalpy as the smectic–liquid transition of cholesterol ester isolated from HDL, and the same temperature as the smectic–liquid transition of cholesterol ester observed by polarising microscopy of heat disrupted HDL. Further, a similar transition is not observed in any of the other lipid or protein components of HDL.

To determine if apo-A1 could be removed from HDL at 37 °C, we incubated intact HDL with turbid suspensions of a synthetic phospholipid, dimyristoyl lecithin (DML). There was clearing of phospholipid turbidity (measured by the decrease in optical density at 640 nm), indicating dissolution of multilamellar phospholipid liposomes. Differential scanning calorimetry tracings of incubated mixtures of HDL and DML are shown in Fig. 2. The addition of HDL to DML resulted in disappearance of the phospholipid pretransition, and broadening and decrease in enthalpy of the main transition. In mixtures containing an excess of HDL, there was complete clearing of turbidity and a single thermal transition with a peak temperature of 25.5 °C (Fig. 2*d*), identical to that observed in complexes of delipidated apo-A1 with DML (Fig. 2*e*). At higher ratios of DML to HDL, there was partial clearing of phospholipid turbidity and thermal transitions with double peaks were observed, the lower temperature component (23.5 °C) corresponding to the gel–liquid crystalline transition of DML multilamellar liposomes (Fig. 2*a*), and the higher temperature component (25.5 °C) to phospholipid–apoprotein complexes (Fig. 2*e*).

Phospholipid–apoprotein complexes, prepared from the delipidated apoproteins of HDL, are disks of phospholipid bilayer about 110×55 Å (ref. 15), which typically appear stacked on edge in negatively stained EM preparations[16]. Such structures were identified in all incubated mixtures of HDL and DML (arrow, Fig. 3*a*), and not in control preparations (Fig. 3*b*). The calorimetric and EM experiments indicate the presence in these mixtures of discoidal DML–apoprotein complexes containing a phospholipid bilayer. In optically clear mixtures (containing no uncomplexed phospholipid), more than 95% of spherical particles observed by EM were between 135 and 210 Å in diameter (for example mean diameter ± s.e.m. = 145 ± 5.1 Å ($n = 150$) in a mixture cointaining 50% DML/50% HDL apoprotein). Since more than 95% of the spherical particles observed were larger than those present in control HDL preparations (Fig. 3*b*), an increase in size of the HDL particle appears to accompany formation of phospholipid–apoprotein complexes. This finding was confirmed by recentrifugation at d 1.125 g ml^{-1} of HDL_3 (1.125–1.21 g ml^{-1}) previously incubated with DML. A major portion of the HDL_3 was found to float between 1.063 and 1.125 g ml^{-1} and compositional analysis showed this was not due to uptake of phospholipid by the HDL_3. The increased size and decreased density of HDL_3 resulting from incubation with DML is consistent with fusion of lipoprotein particles secondary to the removal of apoprotein. Further, the d 1.25 g ml^{-1} infranatant was found to be enriched in DML and apo-A1, indicating the presence of phospholipid–apo-A1 complexes.

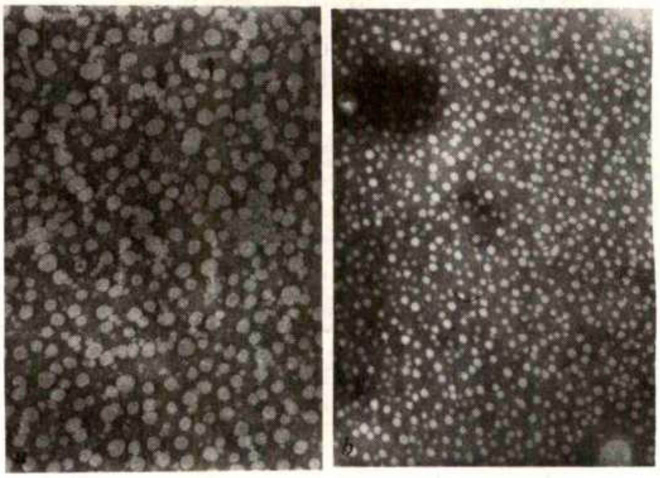

Fig. 3 Electron micrographs, negatively stained with Na phosphotungstate, *p*H 7.3. *a*, DML and HDL, (DML/HDL_3 apo-protein = 2/1). Disks stacked on edge are shown by the arrow. *b*, Control HDL_3 preparation. Magnification of original ×33,000.

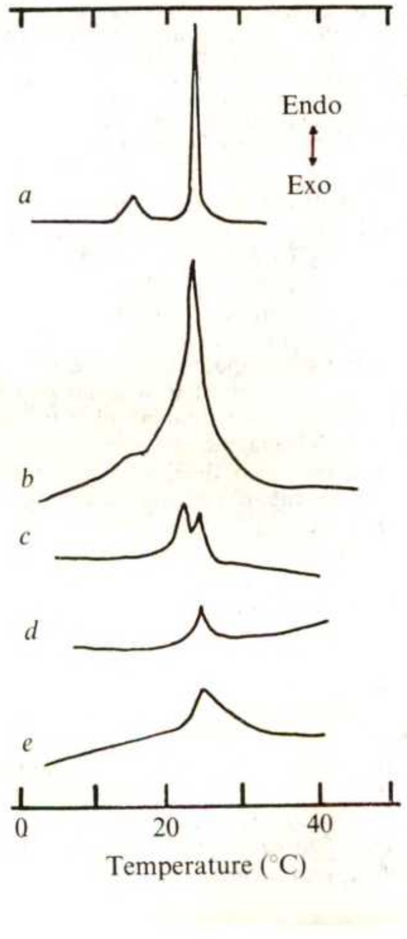
Fig. 2 Differential scanning calorimetry tracings of incubated mixtures of DML and intact HDL: *a*, DML alone; *b*, DML and HDL (DML/HDL apoprotein = 12:1, w/w; *c*, DML and HDL (4:1); *d*, DML and HDL (1:1:2); *e*, DML and apo-Al (1:1.2). HDL (4–15 mg per ml protein) prepared by centrifugation was added without further concentration to unsonicated turbid suspensions of DML (about 4 mg ml^{-1}). DSC experiments were performed with 75 λ aliquots of mixtures of HDL and DML incubated under N_2 at 37 °C for 12 h, by which time all changes in turbidity were completed. The tracings were recorded at different sensitivities. Apo-Al and apo-Al–DML complexes were prepared as described previously[11].



The interaction of the apo-A1 of intact HDL with synthetic phospholipids suggests a possible mechanism for modification of cell membranes. A detergent-like solubilisation of areas of membrane determined by characteristics such as lipid fluidity and cholesterol content could allow an efficient and selective regulation of membrane properties.

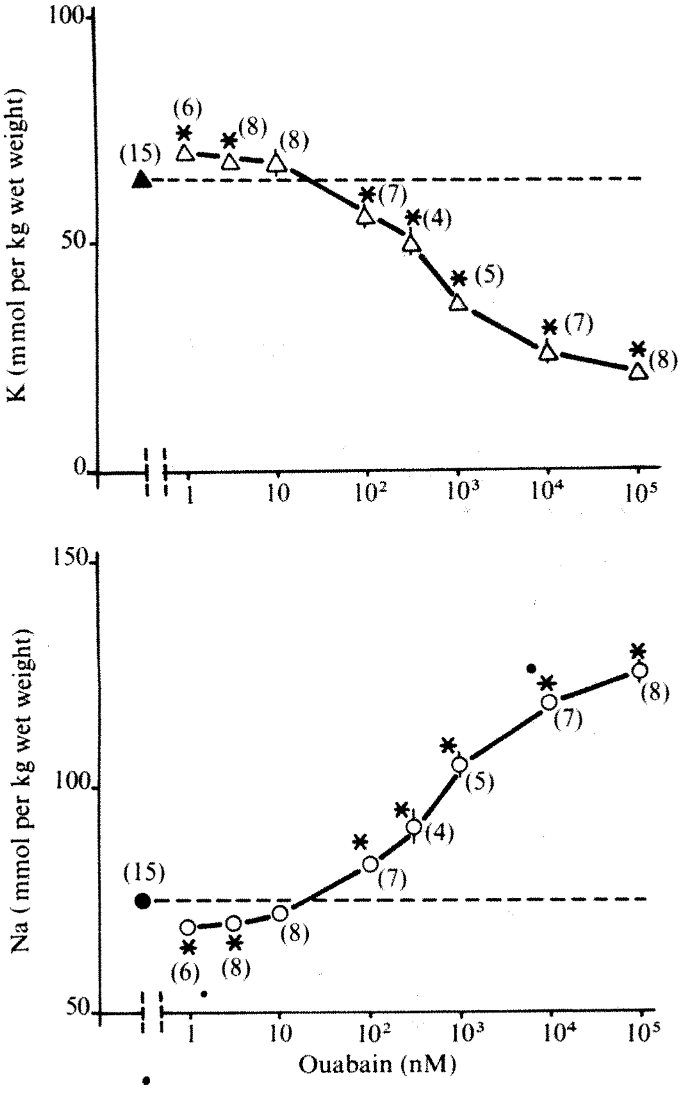
Binding sites related to ouabain-induced stimulation or inhibition of the sodium pump

THE concentration of free cardiac glycosides in the blood of patients treated for heart failure ranges between 1 and 5 nM (refs 1–3). Studies on human heart slices have shown that, within this range of concentrations, digitoxin does not inhibit the sodium pump but does stimulate ^{42}K uptake[3]. Similar observations have been made with isolated guinea pig atria: low concentrations of ouabain (near 1 nM) stimulate ^{42}K uptake whereas higher concentrations inhibit it[4]. These results are in agreement with recent electrophysiological observations on Purkinje fibres showing that low doses of ouabain produce changes in the K gradient that reflect stimulation of the sodium pump[5]. It has also been observed that the stimulation of the sodium pump by ouabain is associated with a positive ionotropic effect[6]. Earlier studies with guinea pig atria[4] and other preparations[7–9] showed that the binding of ouabain occurs on non-specific and specific sites. The specific binding is fitted by a Langmuir curve with an equilibrium constant close to that estimated by measuring the inhibition of the sodium pump. We report here the existence of a binding with a higher affinity associated with the stimulation of the sodium pump.

Fig. 1 Na and K content of stimulated left guinea pig atria incubated for 3 h at 30 °C in the presence of various concentrations of ouabain. Abscissa: ouabain concentration. Ordinate: ionic content determined, after mineralisation, by atomic absorption spectroscopy[11]. Each point represents the mean of a number of individual determinations given between brackets. The limits of s.e. of mean are reported when they exceed the diameter of the symbol. The asterisk indicates that the ionic content of treated atria was different from controls ($P < 0.02$). The dotted line indicates the mean content of controls (closed symbols).



Experiments were carried out with isolated left guinea pig atria bathed at 30 °C in physiological solution (mM: NaCl 137, KCl (unless otherwise stated) 6, $CaCl_2$ 1.82, $MgCl_2$ 0.105, $NaHCO_3$ 11.9, glucose 5.5) equilibrated with a mixture of 95% O_2 and 5% CO_2. The atria were electrically stimulated at a rate of 3.3 Hz (stimulus of 10 ms, strength at least twice threshold); their resting tension was ±500 mg.

Figure 1 shows the changes in K and Na contents measured after an incubation of 3 h in the presence of various concentrations of ouabain. At 1 nM and 3 nM ouabain, the Na content was lower and the K content was higher than in control preparations. Since the inulin diffusion space was not modified, these changes reflect a stimulation of the sodium pump. Higher concentrations of ouabain evoked a gain in Na content and a fall in K content, due to the well documented inhibition of the sodium pump[9,10].

The uptake of ouabain has been measured in the same experimental conditions. ^{3}H-ouabain was added together with ^{14}C-inulin in the incubation fluid. This procedure allowed us to correct tissue ouabain uptake for extracellular ouabain content. Cellular ouabain uptake showed both a linear and a saturable component, confirming earlier results obtained with ouabain concentrations ranging from 30 to 10^3 nM. This uptake was found to fit the equation[4]

$$U = aC_m + \frac{bC_m}{(C_m + K_b)} \qquad (1)$$

where U is the tissue concentration corrected for cardiac

Table 1 Ouabain content of guinea-pig atria corrected for cardiac glycoside in the inulin space

Stimulated left guinea pig atria were incubated for 3 h in the presence of increasing concentrations of ouabain. The ^{14}C-inulin space was estimated for each atrium. The radioactivity was measured as reported before[11]. Values are presented as means ± s.e. of mean. The number of determinations is given between brackets. The incubation time of 3 h was sufficient for complete equilibration, except for ouabain 1 nM and 6 mM KCl. For the latter concentration, the equilibrium content reached after 4 h was equal to 2.1±0.09 nmol kg^{-1} ($n = 8$). The experimental observations are compared with values of U calculated from equation (1) using for the parameters the values estimated for ouabain concentrations between 3 and 10^3 nM. The latter were for 6 mM KCl: a (l per kg wet weight) 0.319, b (nmol per kg wet weight) 372, K_b (nM) 389; for 2.7 mM KCl: $a = 0.206$; $b = 219$; $K_b = 193$.

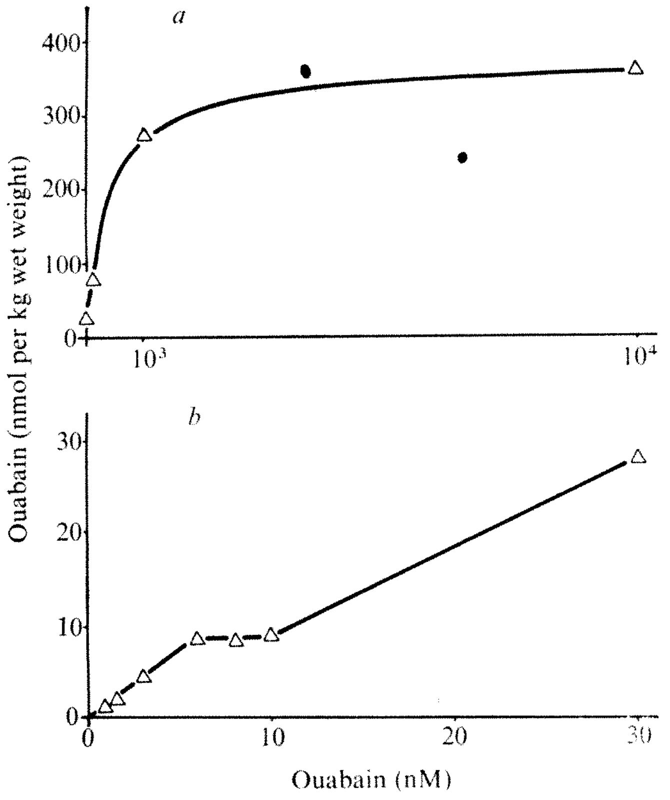

Fig. 2 Specific uptake of ouabain by guinea pig atria. Ordinate: tissue content of ouabain corrected for cardiac glycoside concentration in the inulin space and for the non-specific uptake aC_m. Abscissa: concentration of ouabain in the incubation fluid. Experiments were performed at 30 °C. The ^{14}C-inulin space was estimated for each preparation. The limits of s.e. of mean are shown when they exceed the diameter of the symbol. The number of determinations is given on the graph. Radioactivity was counted as reported before[4,11]. The lower concentrations in the range covered in *a*, are shown on an expanded scale in *b*.

glycoside content of inulin space, C_m is the cardiac glycoside concentration in the medium, a is the proportionality constant for the linear non-saturable uptake, b is the capacity and K_b is the equilibrium constant for the saturable binding sites. Values of the constants computed as described previously[4] are reported in Table 1*a*. The value of a, the non-saturable uptake constant has been estimated in two other experiments. By isotopic dilution, using a large excess of non-radioactive ouabain, constant a was 0.353 ± 0.0216 l kg^{-1} ($n = 12$). When ouabain uptake was measured in the presence of a large excess of digitoxin acting as a competitor[4] the nonspecific uptake of ouabain yielded a value of constant a equal to 0.358 ± 0.012 l kg^{-1} ($n = 4$).

The saturable ouabain uptake was obtained by subtracting the non-saturable uptake from the total uptake at ouabain concentrations ranging from 30 nM to 10^4 nM (Fig. 2*a*). The concentration of ouabain at which half of the saturable binding sites were occupied was equal to 389 nM, a value close to the concentration producing a 50% inhibition of the sodium pump (500 nM).

As shown in Table 1*a* for ouabain concentrations higher than 10 nM, there was a good agreement between experimental and computed ouabain tissue contents. At ouabain concentrations between 1 nM and 10 nM, ouabain tissue content was higher than that expected from equation (1) using the parameters estimated for ouabain concentrations between 30 nM and 10^3 nM.

Figure 2 illustrates the relation between ouabain concentration and specific ouabain binding. It shows two saturable components: one at concentrations ranging from 30 to 10^4 nM (Fig. 2*a*) and the other at ouabain concentrations between 1 and 30 nM (Fig. 2*b*). This indicates the existence of a high affinity and of a low affinity uptake process. The capacity of the high affinity process is only 3% of the capacity of the low affinity one. When the relation between specific binding and ouabain concentration was plotted according to Hill[10], the slope was equal to 2 for the high affinity binding whereas it was 1 for the low affinity binding. This analysis allowed to estimate that the concentration producing a 50% saturation of the high affinity binding was 2.5 nM.

In isolated mammalian cells[7] and in smooth muscle[8], extracellular potassium (K_o) competes for both the binding and the inhibitory effect of doses of ouabain higher than 10 nM. Changes in atria excitability, observed when K_o is lower than 2 mM and higher than 8 mM, allowed a limited study of the effect of K_o on high- and low-affinity binding (Table 1). In KCl 2.7 mM, the apparent equilibrium constant of the low-affinity binding was lower than in KCl 6 mM, and the high-affinity component of the binding was observed at lower ouabain concentrations. These observations suggest that the binding of ouabain to both high-affinity and low-affinity sites is to the sodium pump.

The present findings indicate that two populations of sodium pumping sites might coexist. Recent reports have shown that external Na inhibits the sodium pump by an allosteric mechanism[12,13]. It might be that the high- and low-affinity ouabain binding sites are different states of the same population of receptors. Further experiments are required in order to explore these possibilities.

Clarification of role of ATP in red-cell morphology and function

RECENTLY there has been a tendency to ascribe many energy-dependent functions of other types of cells to red cells. The widespread belief that red cell form and deformability depend on cellular ATP levels and that membrane internalisation is an energy-dependent phenomenon are cases in point[1–4]. ATP has indeed been shown to control phagocytosis, pinocytosis and locomotion in white cells; the confusion over whether it is pinocytosis (which requires energy) or endovesicle formation (which does not) that occurs in erythrocytes may be due to the observation[5] of the former phenomenon in erythrocyte precursors (erythroblasts and reticulocytes). To establish that pinocytosis occurs also in the ultimate cell of the series—the erythrocyte—it is necessary to demonstrate that internalisation of the cell membrane is dependent on energy; and thus on temperature, *p*H, time, and ATP. This is not the case and results of the investigation described here show that ATP does not directly control either the form and deformability or membrane internalisation of red cells and that phenomena secondary to ATP depletion are responsible for the changes induced.

ATP depletion of red cells was accomplished by incubating washed red cells at 37 °C in either a glucose-free Tris-buffered saline medium or in the same medium containing 1 mM iodoacetate and 0.2% glucose. In both the systems the ATP content of the red cells at various periods of incubation was measured by luciferin–luciferase enzyme assay. The deformability of red cells was determined using the Ektacytometer[6]. Membrane internalisation was produced by treatment with chlorpromazine in the concentration range 0.3 to 0.5 mM, and internalisation of membrane demonstrated by morphological observations using phase contrast, transmission and scanning electron microscopy and by measurement of the deformability and osmotic fragility of cells.

Figure 1 shows the ATP content and form of human red cells as a function of incubating time in two media. In the glucose-free medium the discocyte–echinocyte transformation occurs by a progressive increase of echinocytes which are formed in the presence of discocytes, thus demonstrating heterogeneity of the morphology of the population before complete ATP depletion.

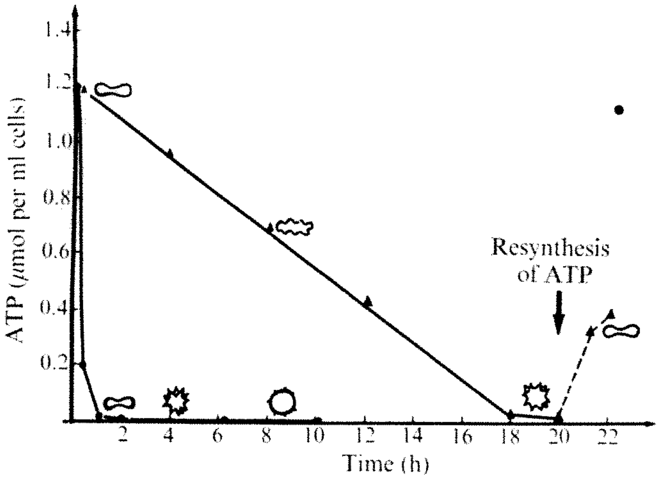

Fig. 1 Changes in ATP content and red-cell morphology with incubation time in different isotonic media: ●, changes obtained by incubation of cells in Tris-buffered saline containing 1 mM iodoacetate. ▲, Changes after incubation in Tris-buffered saline containing no glucose. All the incubations were carried out at an haematocrit of 5%. The *p*H was maintained at 7.4 and the temperature at 37 °C during the whole course of incubation.

When erythrocytes were incubated in a medium with iodoacetate it was possible to maintain discocytic red cells with zero ATP. By prolonging incubation time to 3 or 4 h, a progressive and complete discocyte–echinocyte transformation took place in the presence of iodoacetate. This shows that shape changes will ultimately, though not initially, be caused by effects secondary to ATP depletion that is; by alteration of the ionic equilibrium, loss of cations, and modification of the integrity of the membrane.

For the same cellular concentrations of ATP we can obtain red cells in various morphological states, suggesting strongly that the ATP concentration *per se* does not control cell shape and that ATP is only necessary for maintaining the integrity of other systems that are responsible for the discocytic form. Weed[7] has postulated that ATP-Ca^{2+} ratio is important in controlling form and deformability; and although we have not measured Ca^{2+} levels in the cells during these incubations, we have obtained identical results with incubating media containing chelating agents EDTA and EGTA which were used for the purpose of ruling out the possibility of external Ca^{2+} penetrating the cells during or after ATP depletion. Deformability data shown in Table 1 demonstrate that normal discocytes and discocytes with zero ATP have identical deformabilities. In both of the incubating media reduction in deformability could only be detected after the sphero-echinocyte stage has been reached. Measurements of red cells treated with lysolecithin permitted us to evaluate deformability changes in echinocytes with normal ATP levels. Here again, decrease in deformability could only be detected after the sphero-echinocyte stage had been reached.

Deformability of red cells measured at 4 °C and 37 °C was almost identical.

A dilute suspension (1%) of washed human red cells (discocytes) treated with 0.3 mM chlorpromazine underwent membrane internalisation and were transformed into spherocytes. These spherocytes with endovesicles (Fig. 2) were undeformable (Table 1) and had increased sensitivity to osmotic stress (50% haemolysis at 225 mOsm compared to 50% haemolysis at 140 mOsm for discocytes). When we treated discocytes having no ATP with 0.3 mM chlorpromazine we obtained exactly the same results. These spherocytes also had endovesicles (Fig. 2), reduced deformability and identical increased sensitivity to osmotic stress. Thus the absence of a role for ATP in membrane internalisation in red cells was clearly demonstrated.

The results presented here indicate that in our experimental conditions with intact red cells a direct role of ATP in red-cell membrane function could not be demonstrated. To demonstrate that membrane internalisation could be an energy-dependent phenomenon one should avoid inducing ATP depletion and at the same time a change of red cell shape. According to Deuticke a fixed concentration of chlorpromazine forming vacuoles in a discocyte would not be active on an echinocyte; that is, endocytosis would not

Table 1 Correlation between red-cell shape, ATP content and ability to deform in a free shear field

Red-cell shape	ATP content (μmol per ml RBC)	Average red-cell dimensions* No stress (μm)	At a shear stress of 750 dyne cm^{-2} (μm)
Discocytes	1.2	8.0	16.5
	0.0	8.0	16.5
Echinocytes III	1.2 LPC	5.5	16.0
	0.0	5.5	16.0
Sphero-echinocytes	1.2 LPC	5.5	8.0
	0.0	5.5	8.0
Sphero-stomatocytes with endovesicles	1.2	5.5	6.5
	0.0	5.5	6.5

Red-cells were suspended in a viscous dextran solution (0.14 Poise) and subjected to a shear stress of 750 dyne cm^{-2}. LPC = lysophosphatidylcholine-treated red cells.

*The average red-cell dimensions represent either the diameter of the disk or sphere when no stress is applied, or—when cells are deformed—the size of the larger axis of the ellipse obtained under stress.

occur in the latter cell. In fact we can show that echinocytes with normal or reduced ATP levels can be induced to form endovesicles at higher concentrations of chlorpromazine.

Another argument against energy requirement for membrane internalisation is that identical endovesicle formation was obtained at 4 °C and 37 °C. Neither was *p*H dependence found, in particular for low values compatible with complete solubility of the drug. A false *p*H dependence should result from precipitation of the drug at figures above 7.4.

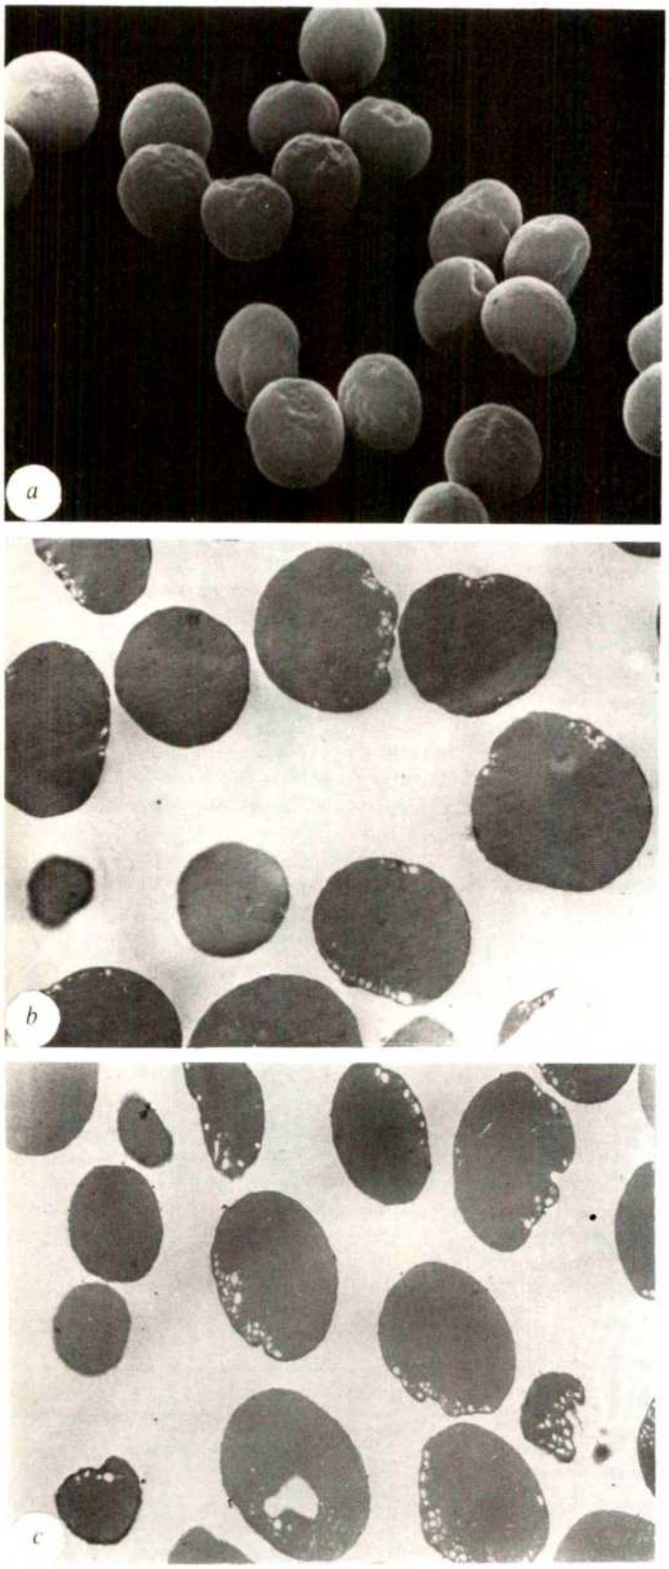

Fig. 2 *a*, Spherostomatocytes obtained by treating normal human discocytes with 0.3 mM chlorpromazine as seen after fixation in scanning electron microscopy. *b*, Endovesicles in spherostomatocytes after treatment with chlorpromazine of red cells containing normal ATP as seen in transmission electron microscopy. *c*, Endovesicles in spherostomatocytes containing no ATP. Red cells were incubated at 37 °C with 1 mM iodoacetate, then treated with chlorpromazine and observed using electron microscopy.

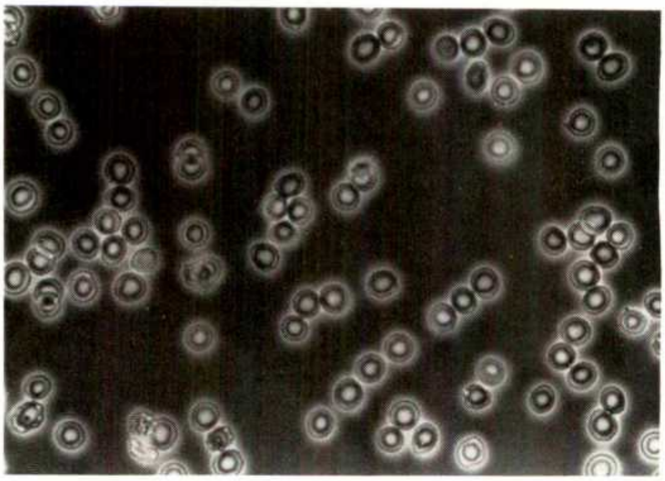

Fig. 3 Red cells incubated 1 h at 37 °C in a Tris-buffered medium containing 1 mM iodoacetate; ATP was < 0.05 μmol per ml red cells. Cells were fixed in 1% glutaraldehyde and observed with a phase contrast microscope (magnification × 290). 95% of the cells are discocytes, 5% are echinocytes 1 to 3.

A last point is the absence of time dependence since vacuoles are abundantly formed very rapidly (within seconds) as is shown by using high concentration of the chemical agents and rapid fixation of the red cells. During the same experiment no measurable ATP depletion could be detected.

Our results are difficult to compare with those using ghosts, as it can be considered that haemoglobin-free red cells represent a very different model.

In contrast, white cell deformability, phagocytic capacity and locomotion are all strong functions of temperature and are inhibited by depletion of cellular ATP levels. Our results, which conclusively show that red-cell form, deformability and membrane internalisation are not energy-dependent functions, taken together with those of others for white cells, strongly suggest that these two cells have different membrane systems for controlling these functions.

We think our data are most easily interpreted by a physicochemical hypothesis as proposed by Singer and Sheetz[8]. According to them, amphiphilic molecules are asymmetrically distributed in the membrane, that is preferentially in the interior part of it for cationic compounds, thus leading to shape changes and vacuole formation.

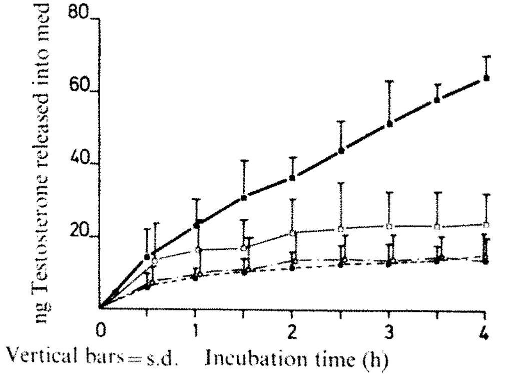
Do androgens increase Leydig cell sensitivity to luteinising hormone?

TARGET tissue responsiveness to hormones is not a static phenomenon, but is often influenced by the endocrine situation. For example, the sensitivity of the Leydig cell in the rat to luteinising hormone (LH) stimulation is not constant but gradually increases during prepubertal development[1]. Moreover, during treatment of hypogonadism in the human male, human chorionic gonadotrophin (hCG) therapy is often increasingly efficacious in stimulating testosterone secretion after repeated injections—a probable manifestation of induced target cell sensitivity. It is possible that androgen receptors in the Leydig cell[2,3] are involved in the regulation of these changes in sensitivity. They are specific for testosterone and dihydrotestosterone[4,5] and are distinct from the oestrogen receptors in the same cell[3,6]. We have investigated a possible role for these androgen receptors using the testicular feminised male (Tfm) rat. This rat has a male genotype and abdominal or inguinal testes, but a typical female phenotype because of a genetically determined lack of androgen receptors and a generalised target organ insensitivity to androgen[7]. We report here that the Leydig cells of the Tfm rat testis have much smaller number of LH/hCG receptors than normal, and this is associated with a low sensitivity to hCG.

To determine whether the responsiveness of Leydig cells of Tfm rats to hCG differed from that of normal males, we incubated Tfm and normal testes with the same dose of hCG. Figure 1 shows the response in terms of testosterone released into the medium. The Tfm testes exhibited a markedly impaired response, with treated testes releasing the same quantities of androgen as did control, unstimulated testes.

What defines the level at which a tissue will respond to a hormone stimulus? Most workers agree that the number of hormone receptors is one of the primary factors controlling the degree of responsiveness of a target tissue to a hormone. Therefore we investigated whether the Tfm testis had a normal content of LH receptors. Figure 2 shows Scatchard plots and saturation curves of LH binding to membrane receptors isolated from the testes of Tfm rats and their normal litter mates (NL). Although LH receptors in normal and Tfm testes had similar binding affinities, there were many fewer in the Tfm testes, which had approximately 20% of the number found in the normal situation when expressed in fmol per mg of protein and 5–10% when calculated per testis. As there seem to be more Leydig cells in the Tfm rat testis than in normal testicular tissue[8], these results suggest a considerable difference in the number of LH receptors per cell. The lack of response of the Tfm testis to hCG is probably due to the reduction in the number of LH receptors on the Leydig cell membranes. The fact that the Tfm syndrome is characterised by a reduced ability of androgens to exert a physiological and biochemical effect indicates that, in the normal situation, androgens are necessary for the normal induction of LH receptors in the Leydig cell. It is possible that this effect is mediated through the androgen receptor since the Tfm Leydig cells, contrary to the normal situation, have no androgen receptors[5].

Fig. 1 The effect of hCG on testosterone secretion from the testis of Tfm and normal litter mates (NL). Decapsulated testes from Tfm and NL rats ($n = 5$) were incubated with or without 3 ng of hCG in 2 ml of Eagle's tissue culture medium. One testis from each animal was incubated in the presence of hCG and the contralateral testis served as control (without hCG). Incubation was performed for 4 h at 34 °C in a Dubnoff shaker, with a gas phase of 95% O_2 and 5% CO_2. Aliquots (25 μl) were taken from media after various times and testosterone was determined by radioimmunoassay. Vertical bars = standard deviation. ■, NL testes with hCG; □, NL testes without hCG; ○, Tfm testes with hCG; ●, Tfm testes without hCG.



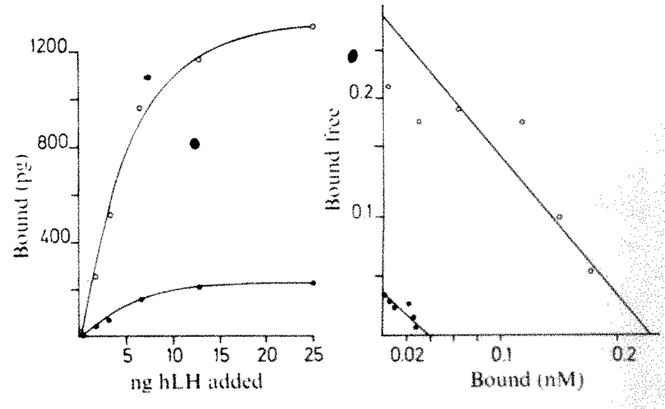


Fig. 2 Binding of human luteinising hormone (hLH) (15,000 IU per mg) to membrane receptors from the testes of Tfm (●) and NL (○) rats. Testes were homogenised in 10 volumes of phosphate-buffered saline (PBS), *p*H 7.4, and centrifuged at 27,000*g* for 30 min. The pellets were washed in the same buffer, recentrifuged and finally resuspended in 3 volumes of PBS containing 0.1% bovine serum albumin (BSA) and 0.1% Neomycin. Fifty μl (300 μg of protein) of membranes were equilibrated at 22 °C for 20 h with 10,000 c.p.m. of ^{125}I-hLH and various amounts of non-labelled hLH (0–20 ng) in a total volume of 200 μl. The pellets were centrifuged at 5,000*g* for 30 min, washed three times in the same buffer and the final pellets counted in a Packard Auto Gamma with 50% efficiency. Five μg of ovine LH (NIH–LH–S19) was used to assess nonspecific binding (6% of total binding). The data were plotted according to Scatchard (bound/free versus bound)[15] and the *x*-axis intercept gives the binding capacity.

Recent studies in our laboratory suggest that this induction takes place during a critical phase of prepubertal development. Treatment of immature male rats with a pure antiandrogen (cyproterone) results in a significant reduction in intratesticular and plasma testosterone without concomitant reduction in plasma gonadotrophin[9]. Similar treatment in the adult male stimulates testosterone secretion due to a central antiandrogen influence[10]. The fact that in the Tfm mouse the Leydig cells are arrested in their cytological development[7] strengthens the evidence for a short-loop positive influence of androgens on the Leydig cells during postnatal differentiation. The human Tfm syndrome, which is similar to that found in rats and mice, is associated with castration levels of LH[11] due to the impaired androgen feedback on the pituitary and hypothalamus. Plasma testosterone levels, however, are in the normal or subnormal male range[12,13], suggesting that Leydig cells in the human Tfm syndrome also show a reduced sensitivity to LH.

Study of the hormonal induction of peptide hormone receptors is the first step to an understanding of the mechanisms underlying fluctuations in tissue responsiveness. Androgens seem not only to induce LH receptors in the Leydig cell but also to stimulate the concentration of prolactin receptors in the rat prostate gland[13], indicating that the receptor-inducing action of the same steroid may be diverse and very complex.

Role of prostaglandin endoperoxide PGG_2 in inflammatory processes

SINCE the discovery that non-steroidal anti-inflammatory agents (NSAI) are potent inhibitors of prostaglandin synthetase[1–3], there has been controversy about the role of primary prostaglandins (PGEs+PGFs=PGs) in inflammatory diseases. A parallel has been demonstrated between the ability of drugs such as indomethacin and aspirin to inhibit cyclo-oxygenase, the initial step leading to the formation of PGs, and anti-inflammatory activity[4–6]. The failure of administered PGs to fully mimic inflammation processes, however, is not consistent with this concept[7,8], and further studies have shown that other products derived from the reaction of cyclo-oxygenase with arachidonic acid (PGG_2, PGH_2 and thromboxane A_2) although quite labile, have biological activities exceeding the potency of the PGs themselves[9,10]. Since these ephemeral mediators are also subject to regulation by NSAI they too must be considered as potential causal agents of inflammation. We have investigated this possibility by examining the action of several NSAI on the total pattern of arachidonic acid oxygenation products. The results indicate that the endoperoxide PGG_2 has a pivotal role in acute inflammation.

During a search for potential non-steroidal anti-inflammatory drugs, one was found to possess a high degree of biological activity, yet it was inactive as an inhibitor in the routine PG synthetase assay[4]. In rat foot oedema, this compound, 2-aminomethyl-4-*t*-butyl-6-iodophenol (MK-447), exhibited good anti-inflammatory activity. Figure 1 shows the dose–response line for oral dosage compared with those for indomethacin and phenylbutazone. The ED_{50} values for indomethacin, MK-447 and phenylbutazone were 2.73, 17.3 and 27.7 mg kg^{-1} respectively. At the level of 50% inhibition of the foot oedema therefore MK-447 was approximately one-sixth as potent as indomethacin, and 1.6 times as potent as phenylbutazone. A similar high degree of activity in suppressing the swelling of the mouse's ear induced by croton oil[11] was also noted. Prostaglandin synthetase inhibitors are efficacious in both assays. It is interesting that the dose–response slopes for MK-447 in both the foot oedema and mouse ear assay, 24.5 and 47.0 respectively, differ from those of the two PG synthetase inhibitors, indomethacin (38.0 and 65.0) and phenylbutazone (38.5 and 65.0). This difference suggested a mode of action for MK-447 not involving inhibition of PG synthetase.

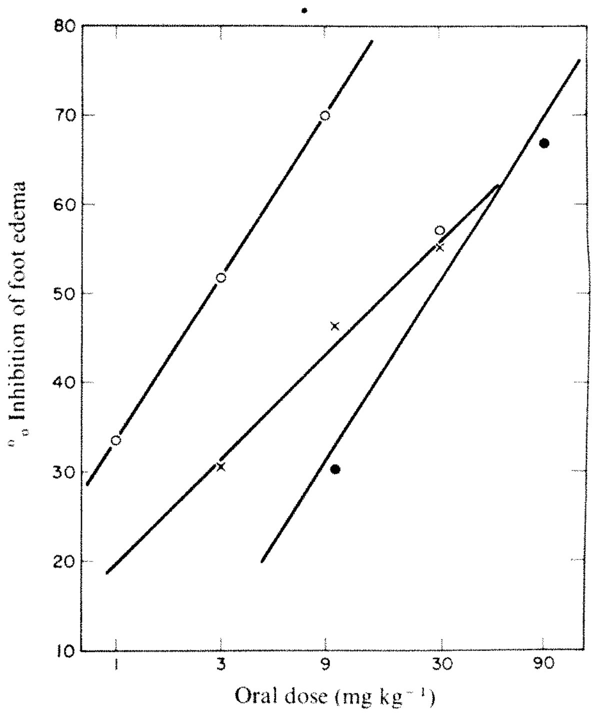

Fig. 1 Comparison of the anti-inflammatory activity of MK-447(×) with the PG synthetase inhibitors indomethacin (○) and phenylbutazone (●) on carrageenan-induced oedema in the rat foot. For indomethacin $y = 38.04 \log x + 33.43$ ($n = 780$ rats;) MK-447, $y = 24.5 \log x + 19.6$ ($n = 96$ rats); phenylbutazone, $y = 38.54 \log x - 5.61$ ($n = 306$ rats). Male Sprague–Dawley rats (150–170 g body weight) were used in groups of 6 each. Compounds to be tested were given by stomach tube in a water solution of 0.5% Methocel used as a suspending agent; 3 ml were given per rat. One hour later, 0.1 ml of 1% carrageenan suspension (Viscarin, Marine Colloids) was injected subcutaneously under the plantar surface of the right hind foot. The volume of the foot was determined immediately by immersion of the foot into mercury up to a previously marked ink spot; the volume of mercury displaced was recorded automatically. The mark was placed on the skin over the lateral malleolus. Three hours later, the volume was measured again; the difference between the two volumes was the swelling. Drug effects were calculated as percentage inhibition of the swelling, taking the swelling of the control group as 100%.

As noted, MK-447 did not inhibit the synthesis of PGs from arachidonic acid when a ram seminal vesicle preparation was used, nor did it inhibit the reaction when oxygen uptake was monitored. In fact, in the absence of cofactors, MK-447 stimulated overall prostaglandin synthesis in a microsomal preparation derived from ram seminal vesicles (Table 1). A similar ability to stimulate the synthesis of PGs was observed in incubated intact mouse ovaries and rat kidney slices (data not shown). These observations indicating that both inhibitors and stimulators of the formation of prostaglandins can suppress inflammatory responses can be interpreted to mean that an intermediate in their formation, apart from the prostaglandins, has a causal role in acute inflammation. The formation of such an intermediate would be expected to be blocked by PG synthetase inhibitors which act at the initial step in the sequence. Levels of such an intermediate would be depressed by the MK-447-facilitated conversion to PGs. In the events leading to the formation of

Table 1 Effects of non-steroidal anti-inflammatory agents on endoperoxides and PGs derived from enzymatic oxygenation of arachidonic acid

Product	Incubation time (min)	nmol per mg protein No additions	MK-447 (100 μM)	Indomethacin (10 μM)	Phenylbutazone (100 μM)	Aspirin (100 μM)
AA	0.5	23	10	43	24	44
PGG_2	0.5	16	6	1	0	0
PGH_2	0.5	4	27	0	20	0
AA	5	7	7	44	22	44
PGG_2	5	13	0	0	4	0
PGH_2	5	5	18	0	11	0
PGs	5	8	15	0	7	0

Values in each category represent a minimum of five experiments. Total radioactivity recovered was greater than 75% in each case and reproducibility of the values for each individual experiment was ±6%. Microsomes were prepared from ram seminal vesicles as described before[14]. The compounds were preincubated with 500–600 μg of microsomal protein in 0.2 ml of 0.1 M potassium phosphate buffer, *p*H 7.5, for 5 min at 25 °C. The reactions were initiated by the addition of labelled arachidonic acid (22 nmol containing 0.25 μCi of ^{14}C-1-arachidonic acid) and incubated for the times indicated. They were terminated by adding 0.05 ml of 0.3 M citric acid, and the products and remaining arachidonic acid were extracted into ether precooled to −70 °C. The entire procedure was carried out in the cold. Ether extracts were chromatogrammed at −20 °C on Whatman SG-81 silica-impregnated paper using ether–hexane–acetic acid (85:15:0.1) as described[24]. Incubation for 0.5 min resulted in the formation of only trace amounts of PGE_2 and $PGF_{2\alpha}$.

PGs from arachidonic acid (AA), that is $AA \rightarrow PGG_2 \rightarrow PGH_2 \rightarrow PGs$, either PGG_2 or PGH_2 would qualify as such an inflammatory agent. The overall sequence of these reactions is depicted in Fig. 2.

As Table 1 shows, approximately half the arachidonic acid is utilised by the microsomal enzyme leading to the formation chiefly of PGG_2 during a 0.5-min incubation. The formation of both endoperoxides is almost completely suppressed by indomethacin. This finding is consistent with an inhibitory effect on the cyclo-oxygenase step[12], the initial reaction in the oxidation of arachidonic acid by PG synthetase. Phenylbutazone inhibits the cyclo-oxygenase reaction less effectively, but significantly alters the ratio of endoperoxides in favour of PGH_2. Aspirin, at relatively high levels, blocks the formation of PG intermediates, a result consistent with an action to acetylate the cyclo-oxygenase[13]. Finally, MK-447 facilitates the enzymatic oxidation of AA to the endoperoxide PGH_2 in 0.5 min and ultimately to prostaglandins as reflected by the value obtained with the longer incubation.

The data presented here show that the quantitative effects of the NSAI studied differ markedly. But these compounds consistently and considerably depress levels of PGG_2, in spite of various effects on the other parameters even including a stimulation of the formation of PGs by MK-447.

Studies of several analogues of MK-447 (data not shown) revealed an obligatory requirement for the free phenolic group for both enzymatic and biological activity; the methyl ether was completely inactive in both parameters. Since phenol itself has been shown to stimulate both the uptake of oxygen by the cyclo-oxygenase and the overall synthesis of prostaglandins[12], a mechanism of action common to both MK-447 and phenol is suggested.

The capacity of phenol to stimulate the synthesis of prostaglandins has been reported to be linked to its ability to facilitate the conversion of the endoperoxide PGG_2 to

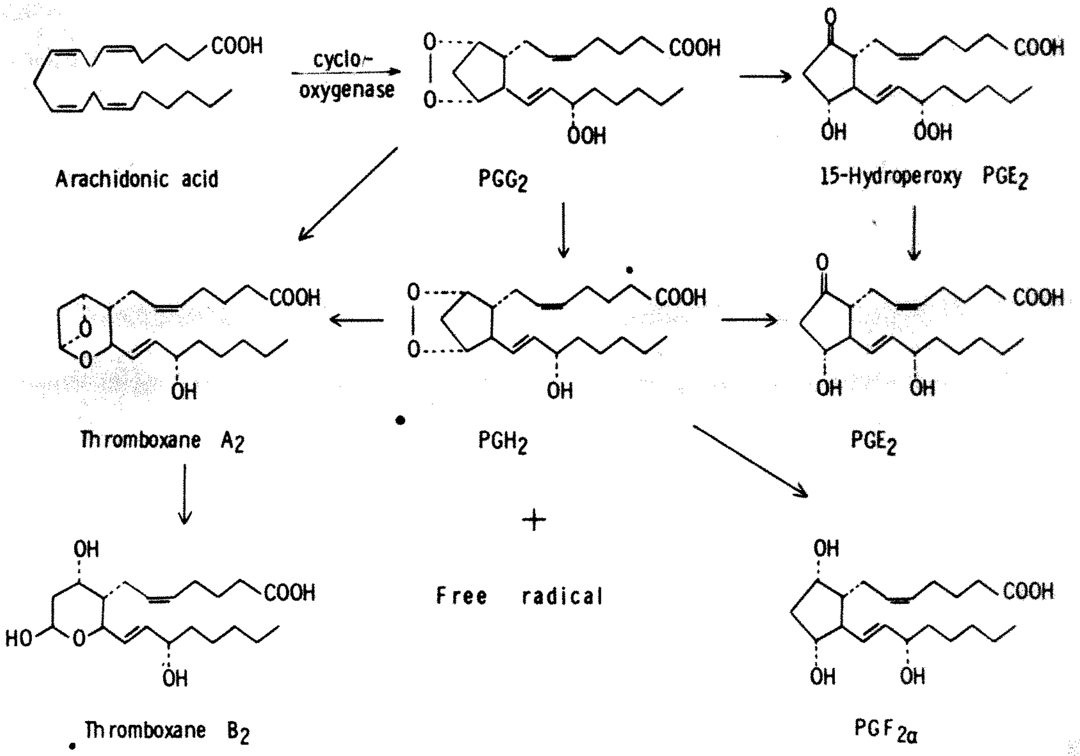

Fig. 2 Enzymatic conversion of arachidonic acid to potential mediators of inflammation.

Table 2 Anti-inflammatory activity of phenol in the mouse ear assay

Phenol (mg)	PMA (mg)	Phenol application relative to PMA	Average change (mg)*	% Inhibition	P

The mouse ear oedema assay[11] was used for these studies, but modified in the use of phorbol 12-myristate-13-acetate (PMA) in place of croton oil as the challenging agent. Groups of 6 mice were used for measurements of the action of phenol and PMA alone (each in 0.1 ml of acetone) and in combination. At times indicated after this challenge a second group received the acetone solution of phenol. Four hours later the mice were killed by cervical dislocation, 8-mm circles of ear were punched out, maintained in standard conditions of humidity and weighed.

*Values represent the increase in weight of the treated compared with untreated ear.

PGH_2 (ref. 14). The corresponding methyl ether is inactive. This effect on the endoperoxide interconversion is a property common to both phenol and methional, a well recognised radical scavenger. Electron paramagnetic resonance studies showed that phenol acts as a free radical scavenger in this reaction, causing stimulation of overall PG synthesis by sequestering the destructive oxygen-centred radical released in the conversion of PGG_2 to PGH_2 (ref. 14). Removal of this radical by phenol not only facilitates the conversion of PGG_2 to PGH_2 but also increases the net turnover of arachidonic acid by minimising oxidative inactivation of cyclo-oxygenase by this same destructive free radical.

Although phenol is inherently quite corrosive to tissues it has been used topically as a pain killer at low doses[15]. We do not know, however, of any report that phenol represses the oedema involved with inflammatory processes. Because of the property common to MK-447 and phenol in stimulating the conversion of PGG_2 to PGH_2 it was interesting to investigate whether phenol itself, like MK-447, had anti-inflammatory activity as measured in one of the *in vivo* test models of inflammation. We used the mouse ear oedema assay[11], but modified it by using phorbol myristate acetate (PMA), a component of croton oil, as the challenging agent. At levels up to 1 mg per site, applied topically, phenol had no significant effect on ear weight by itself when measured 4 h after application (Table 2). At this level a 53.4% reduction in tissue weight occurred when phenol was applied 15 min before the PMA challenge. Significant inhibition was also noted when phenol was applied 1 h after treatment with PMA and read at 4 h. Thus the ability of phenol to mimic the anti-inflammatory properties of MK-447 and their common actions to stimulate the conversion of PGG_2 to PGH_2 and overall PG synthesis are supportive of the concept that the mechanism of action of MK-447 relates to its ability to scavenge free radicals.

The most salient feature of these studies on the oxygenation of arachidonic acid is that levels of the endoperoxide intermediate, PGG_2, alone are depressed by all drugs examined. These data imply that PGG_2 has a pivotal role in acute inflammation. A particularly cogent finding is that one of these drugs, MK-447, can not only cause a depression of PGG_2 in an *in vitro* enzyme system, but also elicit an increased synthesis of PGEs by both microsomal enzyme and by incubated tissues. Thus the demonstrated anti-inflammatory activity of this compound in animal models of acute inflammation, coupled with its ability to stimulate the synthesis of PGs, is not compatible with the concept that primary prostaglandins (PGEs and PGFs) play a key role in inducing the symptoms of inflammation.

Since vasodilation, one component of acute inflammation, is well duplicated by administration of PGE_1 alone[16,17] it is reasonable to suggest that this aspect of the disease relates to the formation of PGEs. But the failure of administered PGEs to fully mimic the oedema[18,19] and pain[20] of inflammation points to PGG_2 as a prime factor in these two components of acute inflammation in view of the data presented here. In focusing on the endoperoxide it is necessary to consider that PGG_2 itself may not be the actual triggering agent in acute inflammation, but merely the precursor of such a substance. Such potential causal agents are shown schematically in Fig. 2. Thromboxane A_2, recently identified as the potent rabbit-aorta-contracting substance, is formed from PGG_2, and its derivation from this endoperoxide may be the preferred pathway[10]. Alternatively, the free radical formed in the metabolism of PGG_2 and tentatively identified as a hydroxy radical[14] may be the inflammatory component liberated in the enzymatic oxidation of arachidonic acid. Such hydroxy radicals have been reported to be very destructive to biological systems and their actions have been linked to inflammatory processes[21,22]. Evidence that peroxy acids are extremely effective pain-inducers[20], and that increased lipid peroxidation accompanies release of lysosomal enzymes[23] adds further credence to the concept that the hydroxy radical may be the relevant oxygenation product of AA in inflammatory diseases. Finally, it is necessary to consider hydroperoxy PGE_2 which also derives from PGG_2. Like PGG_2, 15-hydroxyperoxy PGE_2 is potentially able to liberate an oxygen-centred free radical. In any case we conclude from these studies that the primary PGs as represented by PGE_2 and $PGF_{2}\alpha$ are not the important inflammation-inducing agents obtained from arachidonic acid. Rather the endoperoxide, PGG_2, itself or a non-prostaglandin product(s) derived from it seems to be the major inflammatory agent formed during the enzymatic oxidation of arachidonic acid and blocked by the action of PG synthetase inhibitors, resulting in improvement of the symptoms of inflammation.

We thank Dr E. J. Cragoe for MK-447.

Regulation of autosensitisation to encephalitogenic myelin basic protein by macrophage-associated and soluble antigen

AUTOIMMUNE diseases are characterised by an attack of an individual's lymphocytes against his own body's components, self-antigens. The immunogenicity of self-antigens can be defined operationally by their capacity to trigger lymphocytes bearing specific receptors. We have designed experiments to learn how a defined self-antigen can function as an immunogen *in vitro* and how the form of its presentation to self-recognising lymphocytes may abrogate this immunogenicity. We have found that myelin basic protein (BP) behaves as a self-immunogen when presented to lymphocytes by way of syngeneic macrophages. Moreover, recognition of this self-immunogen can be inhibited by the presence of the same self-antigen in soluble form during the primary lymphocyte–macrophage interaction.

BP is a self-antigen whose amino acid sequence and encephalitogenic determinants have been characterised[1]. Injection of BP in a suitable adjuvant produces in susceptible animals an autoimmune disease called experimental allergic encephalomyelitis (EAE) (ref. 2). The disease is manifested by histological evidence of lymphocytic infiltration of the central nervous system and is expressed clinically by paralysis. For induction of EAE, BP is usually injected in complete Freund's adjuvant; when the same self-antigen is administered in a soluble form without an adjuvant, it is not encephalitogenic. Moreover, under certain circumstances, treatment with soluble BP or its chemical analogues may suppress EAE (refs 3–5). Thus, the development of EAE seems to require suitable presentation of BP to the immune system.

To analyse the immunogenicity of BP, we focused on the initial phase of lymphocyte recognition of BP and separated this process from the subsequent differentiation of effector lymphocytes. We extended a previous observation that recruitment of immunospecific recipient lymphocytes can serve as a means of detecting whether recognition of self-antigens by initiator lymphocytes has occurred *in vitro*[6]. Thus, the recognition of BP was detected by testing the ability of the initiator lymphocytes to specifically recruit lymphocytes in highly inbred strain 13 guinea pigs. A three-phase system was developed (Fig. 1). In stage I monolayers of macrophages were prepared and pulsed with BP antigen. In stage II, the *in vitro* sensitisation phase, initiator lymphocytes were exposed to the BP-pulsed macrophages in the presence or absence of soluble BP. The initiator

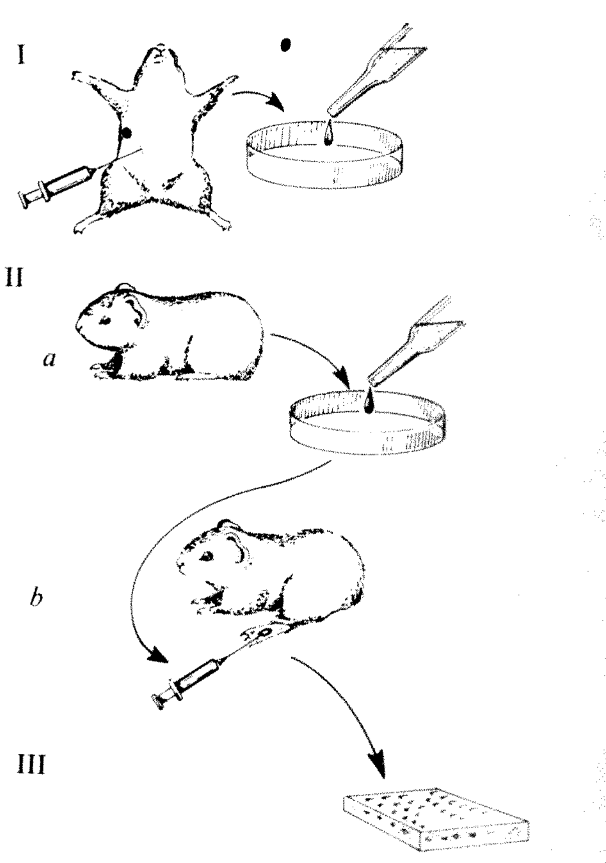

Fig. 1 Experimental format for study of the regulation of autosensitisation to BP. I, BP-pulsed macrophages. Peritoneal exudate macrophages were prepared from unprimed Strain 13 guinea pigs, 4 d after intraperitoneal injection of 15 ml sterile Drakeol, by lavaging the peritoneum with sterile phosphate-buffered saline (PBS) plus heparin, 5 units ml^{-1}. All procedures were then performed in RPMI + 25 mM HEPES buffer without serum at 37 °C; 20 × 10^6 macrophages were allowed to adhere to 100-mm Petri dishes for 2 h, then washed to remove non-adherent cells. The macrophages were then pulsed for one hour with 100 μg ml^{-1} of either BP or G,T. Antigen not associated with macrophages was removed by changing the medium three times. II, Sensitisation of initiator lymphocytes. *a*, 100 × 10^6 unprimed spleen cells were added to the macrophage monolayers. Some groups received soluble BP at a concentration of 100 μg ml^{-1} during lymphocyte–macrophage interaction. After 16 h of incubation of the lymphocytes on the macrophage monolayers, non-adherent cells were removed, then replated for 1 h to re-adhere detached macrophages. No more than 2.5% of the recovered cells seemed to be macrophages and more than 95% were small lymphocytes. The initiator lymphocytes were irradiated with 1,000 R to prevent their replication but not their ability to recruit *in vivo*[6]. *b*, Lymphocytes were then injected into the footpads of syngeneic animals at a concentration of 10 × 10^6 cells in 0.1 ml PBS. Some animals received injections of 10^6 antigen-pulsed macrophages in 0.1 ml PBS into the footpads. The macrophages were obtained from the plates by scraping with a rubber policeperson. Each group contained three or four guinea pigs. III, Assay of proliferative response of recruited lymphocytes. After 13 d the draining popliteal nodes were excised and lymph node cell suspensions of each group were pooled. After 1 h of adherence on plastic Petri dishes to remove debris and dead cells, 5 × 10^5 cells were placed in culture on Greiner microtitre plates. Medium for the assay phase consisted of RPMI + 25 mM HEPES + 1.25% foetal calf serum. 5 × 10^4 unprimed, unstimulated macrophages were irradiated with 2,000 R and added to each culture. Cultures were incubated with 15 μg ml^{-1} of various test antigens for 72 h, then 1 μCi of ^{3}H-thymidine was added for 16 h. Cultures were then collected on a MASH 2 cell harvester and counted in scintillation fluid in a Packard Beta counter. Results are reported as the mean and standard error of the four or five culture wells which comprised each group.

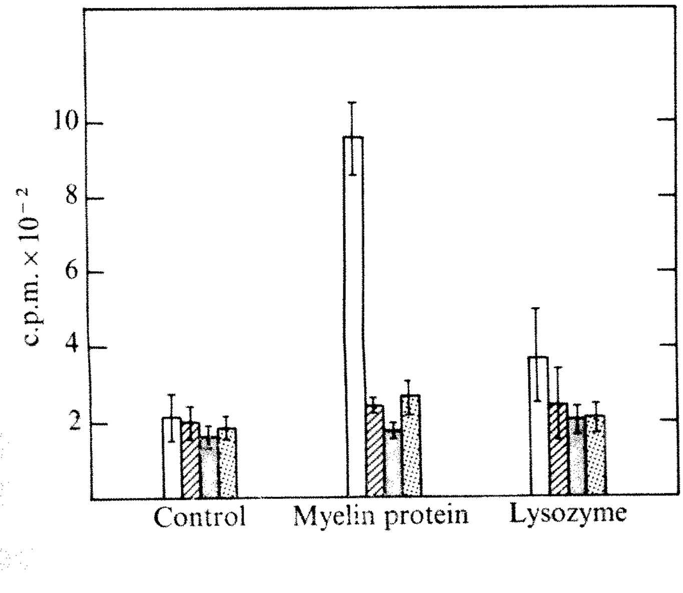
lymphocytes were then collected, irradiated to prevent their proliferation, and injected into syngeneic recipient guinea pigs. In stage III, the assay phase, the DNA proliferative response of recruited lymphocytes to BP served to indicate whether autosensitisation of the initiator lymphocytes had occurred.

The results in Fig. 2 demonstrate that BP was recognised, and triggered syngeneic spleen lymphocytes when presented on macrophages. Initiator lymphocytes were exposed to BP-pulsed macrophages and the lymphocytes were injected into recipient animals. Thirteen days later, recruited lymphocytes from the draining popliteal nodes of the recipient animals reacted to BP with a stimulation index (SI) of 4.4 (Fig. 2). The recruited lymphocytes did not respond to lysozyme, a protein of similar molecular weight and charge. Furthermore, lymphocytes incubated on macrophages not pulsed with antigen failed to recruit lymphocytes responsive to either BP or lysozyme, excluding a potential nonspecific stimulation resulting from the lymphocyte–macrophage interaction.

A control was designed to test whether passive transfer of BP, rather than *in vitro* sensitisation of the initiator lymphocytes could account for recruitment of recipient lymphocytes. Guinea pigs were injected with 500 μg of BP, a dose equivalent to the entire amount present in the *in vitro* culture. The recipient animals showed no evidence of sensitisation to BP (Fig. 2), suggesting that mere passive transfer of antigen could not have triggered active sensitisation to BP *in vivo*. Another control was done to test the possibility that antigen-bearing macrophages that had contaminated the injected lymphocytes acted as the initiators of recruitment. Recipients were injected with 1×10^6 macrophages that had been incubated with BP. This number of macrophages was at least 4 times greater than the number of macrophages actually observed to contaminate the injected lymphocytes. The response to this dose of macrophages was also insignificant (Fig. 2). In other experiments (unpublished) we found that injection of 5×10^6 or more BP-pulsed macrophages was needed to sensitise guinea pigs against BP *in vivo*. Thus, autosensitised initiator lymphocytes and not passively transferred antigen nor antigen associated with macrophages induced the recruitment of recipient lymphocytes against BP in these experiments.

Fig. 2 Immunogenicity of BP on syngeneic macrophages. Incorporation of ^{3}H-thymidine was measured in recruited lymphocytes from the draining popliteal lymph nodes of recipients, 13 d after injection. Recipients received initiator lymphocytes incubated on BP-pulsed macrophages (clear bars) or on macrophages with no antigen (diagonally hatched bars). Other recipients received 10^6 BP-pulsed macrophages (fine stippled bars) or 500 µg of BP directly (coarsely stippled bars). The groups of recruited lymphocytes were incubated without added antigens (control) or with 15 µg ml^{-1} of myelin protein (BP) or lysozyme.



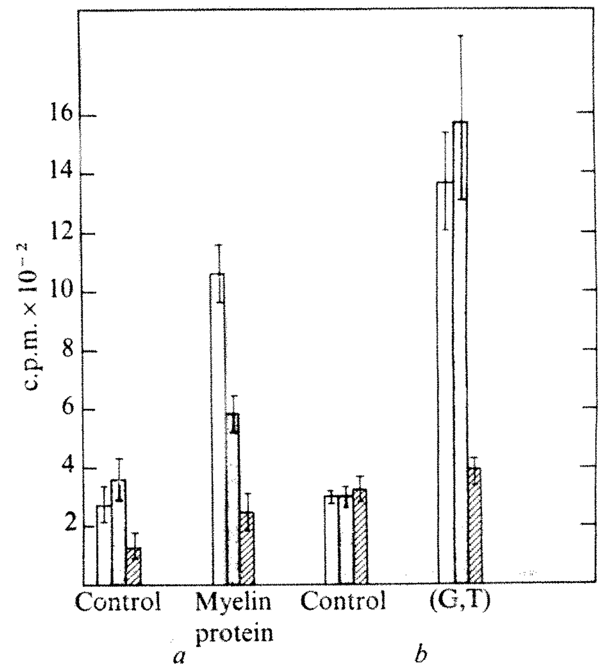


Fig. 3 Blocking of autosensitisation to BP by the presence of soluble BP. Incorporation of ^{3}H-thymidine was measured in recruited lymphocytes from the draining popliteal lymph nodes of recipients 13 d after injection. Recipient animals (Group *a*) received 10×10^6 initiator lymphocytes that had been incubated on BP-pulsed macrophages without (clear bars) or with 100 µg ml^{-1} BP in the culture (stippled bars). Other recipients (diagonally hatched bars) received 10^6 BP-pulsed macrophages. In Group *b* recipients received either 10×10^6 initiator lymphocytes incubated on G,T-pulsed macrophages without (clear bars) or with 100 µg ml^{-1} in the culture (stippled bars). Some recipients received 10^6 G,T-pulsed macrophages directly (diagonally hatched bars). The groups of recruited lymphocytes were incubated without added antigens (control) or with 15 µg ml^{-1} of myelin protein (BP) or G,T.

Next, we tested whether soluble BP might inhibit the activation of self-recognising initiator lymphocytes by macrophage-bound BP (Fig. 3). Initiator lymphocytes exposed to BP-pulsed macrophages recruited recipient lymphocytes to respond to BP (SI=3.9). However, when initiator lymphocytes were exposed to BP-pulsed macrophages in the presence of 100 μg ml^{-1} of BP in the culture medium, the response of the recruited lymphocytes was markedly reduced (SI=1.6; $P<0.001$). As above, injection of BP-pulsed macrophages (10^6) by themselves failed to recruit a response to BP (SI=1.8).

The inhibitory effect of soluble BP was found to be specific (Fig. 3). Initiator lymphocytes incubated on syngeneic macrophages pulsed with a copolymer of glutamic acid and tyrosine (G,T), recruited a response to G,T (SI=4.7). The presence of 100 μg ml^{-1} of soluble BP did not inhibit this response to G,T (SI=5.4), indicating that the soluble BP was not toxic to lymphocytes. The control injection of G,T-pulsed macrophages did not recruit a response to G,T (SI=12). Thus, the presence of soluble BP specifically blocked the induction of sensitisation to macrophage-bound BP and not to an unrelated antigen.

We have demonstrated that healthy guinea pigs possess lymphocytes that can recognise and be activated by a normal self-constituent, BP, when it is associated with syngeneic macrophages *in vitro*. These lymphocytes, which at least when *in vitro* possess receptors for guinea pig BP, can recruit immunospecific autosensitised lymphocytes in a syngeneic recipient. Indeed, normal as well as immune lymphocytes were observed to bind myelin basic protein, presumably by way of specific receptors[7].

In the experiments reported here we did not observe clinical or pathological signs of EEA in guinea pigs receiving 10^7 initiator lymphocytes. In earlier studies in this laboratory[8], lesions of EAE were produced in rats by the injection of about 4×10^8 initiator lymphocytes of thymic origin sensitised *in vitro* against a crude extract of rat brain. Thus, the development of overt EAE might require injection of many more than the 10^7 initiator lymphocytes sufficient to recruit a detectable proliferative response to BP. Although the conditions for induction of disease were not met, our results indicate that receptor-bearing lymphocytes can be induced to immune differentiation by BP associated with syngeneic macrophages. Furthermore, the presence of the same BP in soluble form can block the activation of lymphocytes by immunogenic BP.

These findings suggest that the mechanism involved in the encephalitogenic activity *in vivo* of BP injected with adjuvant might include activation of host macrophages to present BP lymphocytes in an immunogenic form. It has been shown that adjuvants stimulate macrophages[9]. However, it is not clear how macrophages might render BP immunogenic for initiator lymphocytes either *in vivo* or *in vitro*. Studies in this laboratory have shown that antigen extracts from syngeneic tumour cells can be immunogenic for mouse lymphocytes *in vitro* when associated with macrophages[10]. Thus, macrophages seem to have an important function in regulating the immunogenicity of "weak" self- or tumour-antigens, as well as that of extraneous foreign antigens[11].

The blocking of immunogenicity by soluble BP is compatible with the concept that non-immunogenic forms of self-antigens might help maintain natural tolerance to self by blocking lymphocyte receptors and preventing their triggering by immunogenic cell-bound forms of the self-antigens[12]. This concept was originally deduced from studies of recognition and triggering of lymphocytes by self-antigens on fibroblasts or thymic reticulum cells[12,13]. The results presented here strengthen this notion as they were obtained without use of heterologous serum which may have influenced the results of the fibroblast or reticulum cell model systems. The use of purified BP as a self-antigen argues against the possibility that sensitisation was directed against unknown viral or embryonic antigens which might have been expressed in cell culture. Furthermore, induction of autosensitisation in the complete absence of heterologous serum rules out any artefacts resulting from possible sensitisation against foreign antigens present in serum[14]. The recent experiments of Wekerle and Begemann, using an *in vitro* model of autosensitisation against testis antigens provides additional support for the concept of blocking self-antigens as regulators of self recognition[15]. It remains to be demonstrated, however, that soluble self-antigens operate physiologically *in vivo* to prevent autoimmunity by blocking recognition of the same self-antigens in immunogenic form.

Naturally-occurring antibodies to poly(ADP-ribose) in patients with systemic lupus erythematosus

POLY(ADP-RIBOSE) is a biopolymer which is synthesised by poly(ADP-ribose) polymerase in cell nuclei[1]. Its structure and physicochemical characteristics have been reviewed[1]. Its biological function was suggested to be related to DNA synthesis in nuclei[2–4], and there are several reports on its natural occurrence[5–9]. We reported previously that a specific antibody to poly(ADP-ribose) could be produced in rabbits injected with a complex of poly(ADP-ribose) and methylated bovine serum albumin[10]. Kidwell and Mage reported on the presence of poly(ADP-ribose) in HeLa cells and the correlation of its content to cell cycles by a radioimmunoassay[11]. Recently we found that binding activities of the sera of patients with systemic lupus erythematosus (SLE) to ^{14}C-poly(ADP-ribose) were higher than those of the sera of normal individuals, and we suggest that poly(ADP-ribose) as well as antibodies to poly(ADP-ribose) occur naturally in human beings. This paper reports that binding activities of the sera of SLE patients to ^{14}C-poly(ADP-ribose) are attributable to immunoglobulins, mainly to IgG, but not to nonspecific interactions between ^{14}C-poly(ADP-ribose) and IgG; specificity of the binding was verified by inhibition tests using unlabelled poly(ADP-ribose) and 14 related compounds.

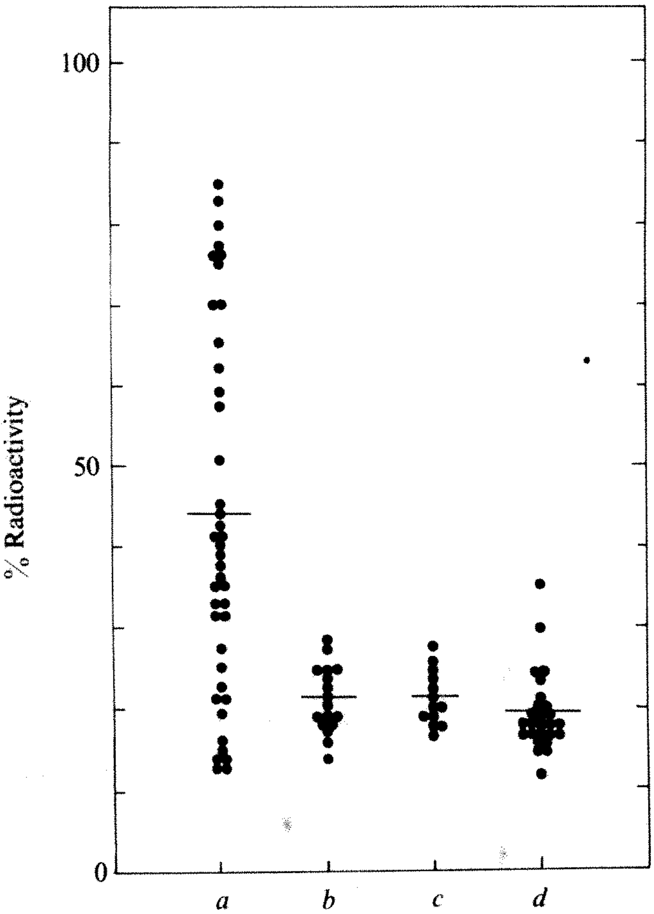
Figure 1 shows binding activities of the sera of SLE patients to ^{14}C-poly(ADP-ribose) tested by a Millipore filter method, as described in the legend to Fig. 1. The binding of the sera of SLE patients to ^{14}C-poly(ADP-ribose) was higher than that of the sera of patients with other diseases or normal individuals. It is well known that antibodies to nucleic acids occur with great frequency in SLE patients[13–15]. Poly(ADP-ribose) is a well characterised biopolymer synthesised by a nuclear enzyme[1] and highly immunogenic[10], and thus, we postulated that high binding of SLE sera to ^{14}C-poly(ADP-ribose) was due to naturally-occurring antibodies to poly(ADP-ribose).

To examine this hypothesis, crude immunoglobulin fractions obtained from five different SLE sera showing high binding activity were applied to a column of Sephadex G-150. As controls, crude immunoglobulin fractions from two sera of different normal individuals were similarly applied to a column. Figure 2 shows profiles of ^{14}C-poly-(ADP-ribose) binding in the fractions. In all SLE sera, ^{14}C-poly(ADP-ribose) binding activity was observed in the 7S as well as the 19S γ-globulin fractions. On the other hand, in the sera from normal individuals, ^{14}C-poly(ADP-ribose) binding activity was extremely low and was found only in the 19S γ-globulin fractions.

To prove that ^{14}C-poly(ADP-ribose) binding in the fraction from SLE patients was attributable to immunoglobulin itself, the double antibody method, using anti-μ and anti-γ chain sera (Behringwerge) was applied to the fraction of Fig. 2*a*, as follows. Amounts of ^{14}C-poly(ADP-ribose), and aliquots of the Sephadex fractions used were the same as in the Millipore filter method. After incubation in phosphate-buffered saline–bovine serum albumin at 37 °C for 1 h, 100 or 200 μl of anti-μ or anti-γ chain sera was added with 20 μl of normal human serum as a carrier. The mixture was further incubated at 37 °C for 1 h, and kept at 4 °C overnight. The precipitate thus formed was collected by centrifugation at 4 °C, washed once with cold PBS and solubilised in an NCS tissue solubiliser and the radioactivity was measured in a liquid scintillation counter. Profiles of ^{14}C-poly(ADP-ribose) binding obtained by the double antibody method coincided very well with those obtained by the Millipore filter method (data not shown).

In addition, F(ab′)$_2$ was isolated from the sera of SLE patients as well as a normal individual, according to the method of Nisonoff *et al.*[17,18] as described in the legend to Fig. 3. ^{14}C-poly(ADP-ribose) binding to the F(ab′)$_2$, as a function of their concentrations, is shown in Fig. 3. All the F(ab′)$_2$ from different SLE patients clearly showed ^{14}C-poly(ADP-ribose) binding, whereas there was practically no binding with F(ab′)$_2$ from the normal individual. These results indicate that the high ^{14}C-poly(ADP-ribose) binding to the sera of SLE patients is attributable to specific interactions between ^{14}C-poly(ADP-ribose) and immunoglobulin, mainly IgG.

Fig. 1 ^{14}C-poly(ADP-ribose) and unlabelled poly(ADP-ribose) were prepared by the method of Sugimura *et al.*[12]. The assay of ^{14}C-poly(ADP-ribose) binding to serum was carried out by a slight modification of the previously described method[10], as follows: A mixture of ^{14}C-poly(ADP-ribose) (3,500 c.p.m., 4 ng) and 10 µl of serum was adjusted to a volume of 1 ml with phosphate-buffered saline containing 0.1% bovine serum albumin, *p*H 7.4 (PBS-BSA), and incubated first at 37 °C for 1 h with gentle shaking followed by 1 h incubation at 0 °C. After incubation, the mixture was poured onto a 0.22-µm pore size (GS WP 025 00) Millipore filter and washed with 3 ml of phosphate-buffered saline, *p*H 7.4 (PBS) at room temperature. The Millipore filter was then dried and the radioactivity was measured, using a Toluene-based scintillator by a liquid scintillation counter (Packard). In the absence of serum, the radioactivity trapped on the Millipore filter was less than 5% of the added ^{14}C-poly(ADP-ribose). The background count was subtracted from all experimental values. The serum was incubated at 56 °C for 30 min before use. *a*, SLE; *b*, rheumatoid arthritis; *c*, patients with other diseases; *d*, normal individuals.



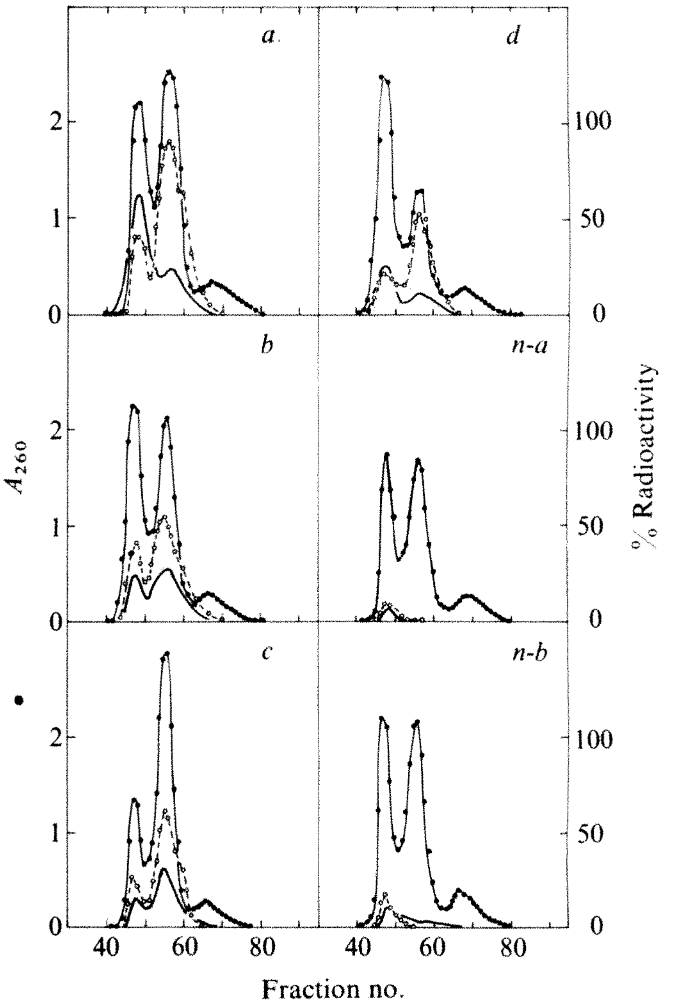


Fig. 2 Sera were diluted twice in PBS and were precipitated in half-saturated ammonium sulphate. The crude γ globulin (1.5 ml) was applied to a column of Sephadex G-150 (1.8 × 84 cm), which had been equilibrated with PBS. Two-millilitre eluate fractions were collected at a flow rate of 10 ml h^{-1}. An aliquot of each fraction (70 µl) was used for the assay of the binding to ^{14}C-poly(ADP-ribose), as described in Fig. 1. Native DNA binding in each fraction was assayed using ^{3}H-native DNA. ^{3}H-native DNA (2,700 c.p.m., 75 ng) was prepared by the method of Botchan *et al.*[16] from cultured mouse myeloma cells (L5178Y). Assay conditions were the same as for ^{14}C-poly(ADP-ribose), described in Fig. 1. Four cases out of five different SLE patients and two normal individuals are presented here. *a*, *b*, *c* and *d*, SLE patients; *n-a* and *n-b*, normal individuals. - - - O - - -, ^{14}C-poly(ADP-ribose) binding; ———, ^{3}H-native DNA binding. ●, A_{280}.

The specificity of ^{14}C-poly(ADP-ribose) binding to the 7S γ-globulin fraction, in five cases of SLE sera, was tested by inhibition tests as shown in Table 1. Inhibition of ^{14}C-poly(ADP-ribose) binding was caused partly by poly(A)·poly(U), poly(A) and poly(I), therefore the ^{14}C-poly(ADP-ribose) binding to SLE sera may represent a sum of cross reactions with antibodies to these nucleic acid forms. To clarify this, the SLE sera were subjected to absorption experiments with poly(A)·poly(U), poly(A) and poly(I). The residual binding of the ^{14}C-poly(ADP-ribose) by absorbed sera was no longer inhibited by poly(A)·poly(U), poly(A) and poly(I), but only by unlabelled poly(ADP-ribose), thereby ^{14}C-poly(ADP-ribose) binding to the SLE sera, shown in Fig. 1, seems

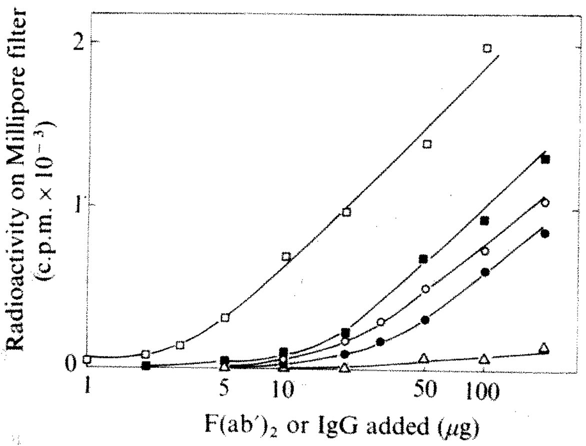

Fig. 3 IgGs of SLE patients *b*, *c*, *d* and normal individual *n-a* were purified from 7S γ-globulin fraction (2nd peak of Fig. 2) by the method described previously[10]. They were digested with 10% crystallised hog stomach pepsin (Sigma) in 0.1 M sodium acetate buffer, *p*H 4.8 at 37 °C for 18 h and neutralised with 1 N NaOH. F(ab')$_2$, thus formed, were precipitated at a concentration of 18% sodium sulphate. The precipitate was once washed with a solution of 18% sodium sulphate, and was dialysed overnight against PBS. The ^{14}C-poly(ADP-ribose) binding assay was performed by the Millipore filter method, as described in the Fig. 1 legend. □, untreated IgG from SLE patient *c*; ■, F(ab')$_2$ from SLE patient *c*; ○, F(ab')$_2$ from SLE patient *b*; ●, F(ab')$_2$ from SLE patient *d*; △, F(ab')$_2$ from normal individual.

to be immunologically specific. Variations in the degree of inhibition, shown in Table 1, may reflect the complexity as well as the state of the disease.

Furthermore, the SLE serum antibodies to poly(ADP-ribose) were most reactive to the poly(ADP-ribose) with 20 repeating ADP-ribose units which was used in the text, and the reactivity of the antibodies was dependent on the chain length of the polymer. This was also true for experimentally induced rabbit antibodies to poly(ADP-ribose).

As native DNA was not a good inhibitor (Table 1) and profiles of ^{3}H-native DNA binding in the fraction of Sephadex G-150 column were different from those of ^{14}C-poly(ADP-ribose binding (Fig. 2), antibodies to poly(ADP-ribose) seem to be completely different from antibodies to native DNA. Antibodies to poly(ADP-ribose) in some SLE patients so far examined still maintained the high levels even after reduction in levels of antibodies to native DNA. The value of the serum antibodies to poly(ADP-ribose) for the judgement of clinical state of SLE patients remains to be studied.

Table 1 Inhibition of ^{14}C-poly(ADP-ribose) binding to 7S γ-globulin fractions by unlabelled poly(ADP-ribose) and related compounds

	SLE patient				
Related compound	*a*	*b*	*c*	*d*	*e*
	% Inhibition				
Poly(ADP-ribose)	82	58	75	55	69
ADP-ribose	5	10	0	10	19
Poly(A)·poly(U)	32	20	14	12	31
Poly(I)·poly(C)	12	6	1	9	17
Poly(A)	25	0	5	2	16
Poly(U)	5	0	4	8	11
Poly(I)	14	0	13	14	19
Calf thymus DNA (native)	4	9	0	7	13
Calf thymus DNA (denatured)	9	0	0	12	11
SV40 viral DNA	0	0	0	4	4
Yeast RNA	12	3	0	7	11

Potassium ion noise currents and inactivation in voltage-clamped node of Ranvier

THE experimental results of voltage noise analyses for the potassium channel system in frog nerve membranes are inconsistent with the theoretical expectations: the measured noise intensity should decrease at positive membrane potentials, where an increase is found[1,2]. The theories[3-7] are based upon the empirical Hodgkin–Huxley equations, and therefore "... cover only the short term responses of the membrane ..."[8]. Our noise experiments were made in the stationary state. A recent report suggests Hodgkin–Huxley kinetics for potassium noise currents measured earlier after changes in membrane potential[9]. Taken together these results suggest, however, that the potassium channel system changes its behaviour in time with respect to its noise pattern, which implies the occurrence of structural changes in time. We show here that the potassium channel system does indeed change structurally during long duration voltage steps.

The mean membrane current changes in time in response to a pulse of constant voltage (voltage clamp). It rises to a

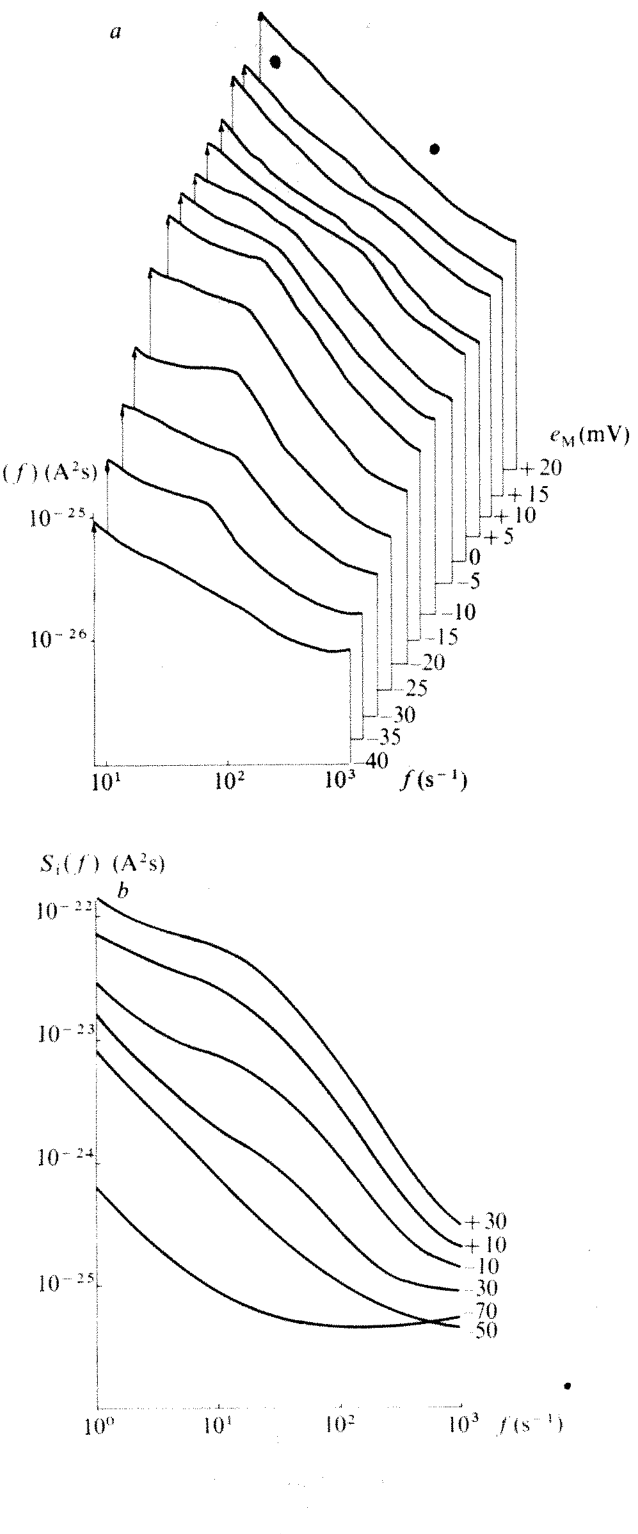

Fig. 1 Spectral densities $S(f)$ of potassium noise currents as a function of membrane potential for one node of Ranvier, at 21 °C. Phase 1 spectra in *a* and phase 2 spectra in *b*. The membrane current was filtered by a two-pole Butterworth high-pass filter with a cutoff at 5 s^{-1}. For phase 1 noise measurements 30–60 voltage steps of 600 ms each were registered per membrane potential. Each signal was further amplified (5,000 times) after a delay of 400 ms to allow the filter transients to sufficiently decay below the membrane noise level[15], and subsequently recorded on analogue tape (bandwidth 0–5 × 10^3 s^{-1}). After low pass filtering (f^{-8}, Butterworth response) the digitalised correlation function estimator, calculated by a HP3721 correlator, was multiplied with a time window after Hann and Fourier transformed. The set of 30–60 Fourier transforms was averaged for each spectrum. For phase 2 noise measurements single voltage steps of 60–100 s were used at each potential. The measurements were started 20–40 s after the beginning of a step to be in the steady state of inactivation. The spectra were obtained in a similar way, but here the averaged correlation function was used instead.

maximum within 25 ms and stays there for pulses shorter than 200 ms (refs 10, 11). Inactivation, that is, a subsequent decrease of the potassium current, occurs with longer pulses. The decrease proceeds in two phases: a relatively fast decline followed by a slower decrease to a non-zero stationary level[12].

We measured potassium noise currents both during the quasi-stationary early part of the first decline in potassium current (here called phase 1) and in the stationary state after the end of the slow decrease in current (phase 2).

Single sciatic motor fibres of *Rana esculenta* were voltage clamped in a setup after Frankenhaeuser[13], designed for low noise performance and for measurement of the absolute value of the membrane current[14]. The sodium system was blocked with TTX (tetrodotoxin, 300 nM in the bathing medium). The mean potassium current was measured with 25-ms voltage pulses, preceded by a 2-s pulse at −100 mV to remove inactivation. The currents were digitised, stored and subsequently analysed in terms of the Hodgkin–Huxley equations. Phase 1 noise measurements were made with 600-ms duration voltage pulses, with current noise analysis in the interval from 400 to 600 ms (ref 15). 60–100-s voltage steps were used for phase 2 investigations, where the noise analysis was started after complete inactivation.

Both in phase 1 and in phase 2, two noise components were found in the spectra (Fig. 1). A relaxation noise component (the humps in the spectra) and a f^{-1} noise component (with spectral intensity $S(f) = c/f$, slope −1 in the graphs). The relaxation noise component (obtained after correction for the f^{-1} noise [16]) has a constant spectral intensity $S(+o)$ at low frequencies and declines with f^{-2} at high frequencies (slope −2). The intersection between the two frequency asymptotes gives the corner frequency f_c.

The potassium channel blocker TEA (10 mM tetraethylammonium chloride in the bath) decreases both components in both phases, as expected[1,2,9]. The effect of TEA, however, differs for the two phases. The phase 1 noise intensity $S(+o)$ is about 10 times smaller than before TEA application, while the remaining intensity in phase 2 is quite large: at least 70% of its unpoisoned value. The mean potassium current behaves similarly. The initial reduction by 10 mM TEA to about 5% of the original value[17,18], is followed, however, by an increase during the period corresponding with the decrease of the potassium current (inactivation) in the unpoisoned state. The final current intensity under TEA is about 50% of its value in the untreated state. The potassium channel system of frog nodes, therefore, changes its properties quite drastically with time.

Investigation of the potassium noise properties confirms this (Fig. 2). The low frequency intensities $S(+o)$ are a function of membrane potential (Fig. 2*a*) and go through a maximum for phase 1 noise (near −20 mV). $S(+o)$ however, shows a different behaviour in phase 2, in accordance with our previous results[2]. The cutoff frequencies f_c (Fig. 2*b*) also behave quite differently with a pronounced dependence on membrane voltage[9] in phase 1 (above −10 mV) but not in phase 2[2,16] (with $f_c \simeq 45$ s^{-1} at 21 °C).

It follows that the potassium relaxation noises in phases 1 and 2 are generated by different sources. Here the frog nerve differs from the squid axon where "phase 2" noise is reported to be related to Hodgkin–Huxley potassium kinetics[19,20]. In frog nodes phase 1 noise is most probably related to the potassium Hodgkin–Huxley kinetics. We calculated the properties of the potassium relaxation noises according to the simplest translation of the Hodgkin–Huxley equations in stochastic terms[3,4], using the Hodgkin–Huxley parameters from the 25-ms voltage clamp experiments. The results (lines in Fig. 2) show that the measured phase 1 intensities $S(+o)$ follow the predicted relation quite well. This parameter may be less sensitive for small deviations from Hodgkin–Huxley kinetics than the kinetic parameter f_c, which shows a deviation. Here partial inactivation present in phase 1, although small, may also have a role. The potassium channel conductance γ_K was cal-

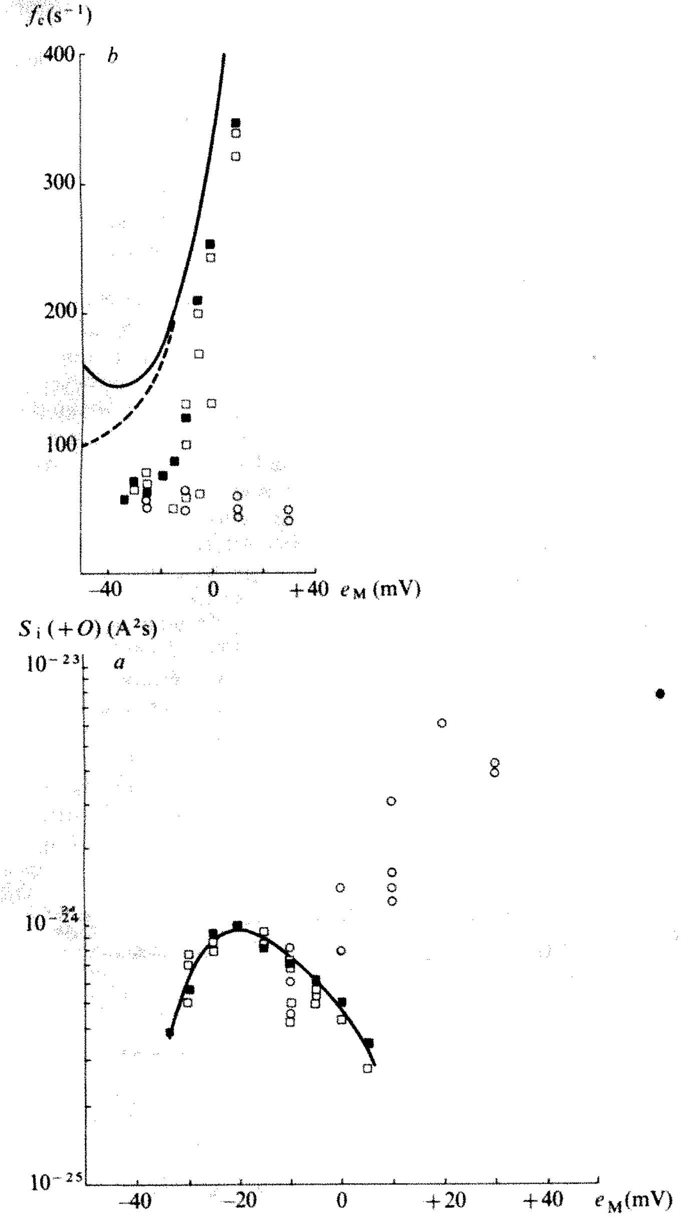

Fig. 2 *a*, Low frequency intensities $S(+o)$; *b*, cutoff frequencies f_c, of the potassium-relaxation spectra of four nodes of Ranvier, at 21 °C, plotted against membrane potential, for noise currents recorded in phase 1 (□) and in phase 2 (○). Lines give theoretically expected values for Hodgkin–Huxley four-gate open–close kinetics (solid), with the voltage clamp parameters of one of the nodes (■); dashed line is $f_c = \dfrac{1}{2\pi\tau_n}$

culated, assuming that all channels are in the open state when the mean potassium conductance $\langle g_K\rangle$ reaches its maximal value $\bar{g}_K$ at a certain positive membrane potential. The channel conductance then follows from[3,7]:

$$\gamma_K = \frac{\sigma_I^2}{\langle I_K\rangle(E-E_K)(1-\langle g_K\rangle/\bar{g}_K)} \qquad (1)$$

with mean potassium current $\langle I_K\rangle$, membrane potential E and potassium equilibrium potential E_K. The variance of the current fluctuations, σ_I^2, was obtained by integration of the one-sided spectrum. This gave the estimate for $\gamma_K = 2.9 \pm 0.4$ pS (three nodes, 12 estimates, at 21 °C). This value, which is close to that reported by Begenisich and Stevens[9] (4.0±0.27 pS, 14 observations at 15 °C) does not depend on membrane potential within its measurable range (−30 to +5 mV).

The subsequent change in behaviour must be due to either conformational changes of the channel system or a new potassium channel system arising during inactivation. Which possibility actually occurs must be left open. With the conformational change assumption, however, the channel conductance in phase 2 can be calculated with equation (1). The phase 2 channel conductance now seems to depend strongly on membrane potential, increasing more than twice in the range from −10 to +30 mV. This implies that equation (1) does not yield the open channel conductance and necessitates the use of a specific channel model[7].

Our results prove that the potassium channel system in frog nodal membrane changes its properties profoundly during long duration voltage steps. Another new result, the difference in pharmacological behaviour with regard to the passage of time after the application of a voltage step, shown here to exist for TEA, may also have practical implications. Bioluminescence of lantern fish (Myctophidae) in response to changes in light intensity

THE characteristic ventral distribution of fish photophores suggests that their luminescence reduces the silhouette when viewed against a background of downwelling light[1–3]. This hypothesis is supported by demonstration of direct neural control of photophores in several species of myctophids and by morphological and behavioural indications that *Tarletonbenia crenularis* matches its luminescence to background illumination by visually monitoring a supraorbital photophore[4,5]. There is similar evidence for other taxa: shallow water leiognathids emit light in response to brief photic stimulation and mid-water squid have photosensitive vesicles which may participate in countershading[6–8]. Here we report photometric measurements of myctophid bioluminescent responses to light levels comparable with those occurring in their environment.

Symbolophorus californiensis (Eigenmann and Eigenmann) bears approximately 70 photophores of about 0.5 mm diameter on ventral and lateral surfaces. When immature, it lacks the brilliantly flashing luminous patches characteristic of many myctophids. It migrates daily from 600 m to or near the surface[9]. Immature specimens in good condition were netted at night by neuston net from RV Velero IV over the San Clemente Basin. They were transferred to containers of surface temperature seawater and held in darkness for experimentation within the next several hours aboard ship. Individuals were placed in a 1-l cylindrical glass jar in an apparatus with which it was possible to continuously record bioluminescence against controlled background irradiance of up to 0.09 μW cm^{-2}. Background irradiance was generated by five Sylvania R1166 glow modulator tubes emitting white light onto a diffusing hemisphere above the specimen chamber. An EMI 9781B photomultiplier, viewing the entire specimen chamber from below, detected bioluminescence. Interference from background irradiance was eliminated by pulsing the glow modulators at 180 Hz in synchrony with a rotating shutter over the photomultiplier tube. The 'on' period for the glow modulators corresponded to the period during which the photomultiplier tube was covered by the shutter. The photomultiplier signal was processed by a Kiethley 840 lock-in amplifier and displayed on a chart recorder with a bandwidth of 70 Hz. Background irradiance was measured with a United Detector Technology 40X radiometer. Tests of the performance of the apparatus showed that a photophore-sized light source, placed 10 cm from the photomultiplier, and producing an estimated irradiance of 5×10^{-5} μW cm^{-2}, could readily be detected against a 0.5-m^2 background producing an irradiance of 8×10^{-2} μW cm^{-2}. Because the 180-Hz glow modulator cycle exceeds the highest visual flicker fusion frequency reported for fish, the apparatus makes it possible for a subject to be exposed to perceptually continuous light while being monitored by a photomultiplier protected from dark current and sensitivity changes caused by excessive light exposure of the photocathode[10].

Six *S. Californiensis*, 26–30 mm standard length, responded similarly to repeated exposures to various background light regimes. Latency of bioluminescence initiation after switching on background lighting was as little as 0.5 s, with averages for four fish being 18.5 (four tests), 7.0 (one), 1.0 (four) and 2.0 s (six). 'Off' responses were similarly rapid but the data cannot be used for a precise measurement. In many instances a probable luminescent startle response of 0.5–1.0 s latency, requiring an average of 4 s from half amplitude on to half amplitude off, precede initiation of sustained bioluminescence (Fig. 1*a* and *b*). Our data cannot be used to estimate how closely the fish match the background irradiance with their photophore emission because the position of the fish is indeterminate. The level of bioluminescence, however, is clearly directly related to background irradiance over part of the background irradiance range. When exposed to a ramp of increasing irradiance, ranging from near 0 to 0.008 μW cm^{-2} over 55 s, bioluminescence also increased in ramp-like fashion (Fig. 1*a*). Assuming a nominal position of 10 cm from the photomultiplier and maximum exposure of the ventral surface of the fish to the photomultiplier, point A in Fig. 1*a* corresponds to an irradiance of 2×10^{-5} μW cm^{-2} at the photocathode of the photomultiplier tube. Further evidence of proportionality of bioluminescence to background light intensity is seen in Fig. 1*b* and *c* where bioluminescence is off scale at 0.05 μW cm^{-2} background and considerably less at 0.002 μW cm^{-2} background. Bioluminescence is inhibited when the background reaches about 0.09 μW cm^{-2} and reappears when the background is reduced to 0.02 μW cm^{-2}, an effect that may be due to visual light adaptation because bioluminescence can be maintained to 0.08 μW cm^{-2} background irradiance when the background is cycled from dim to bright.

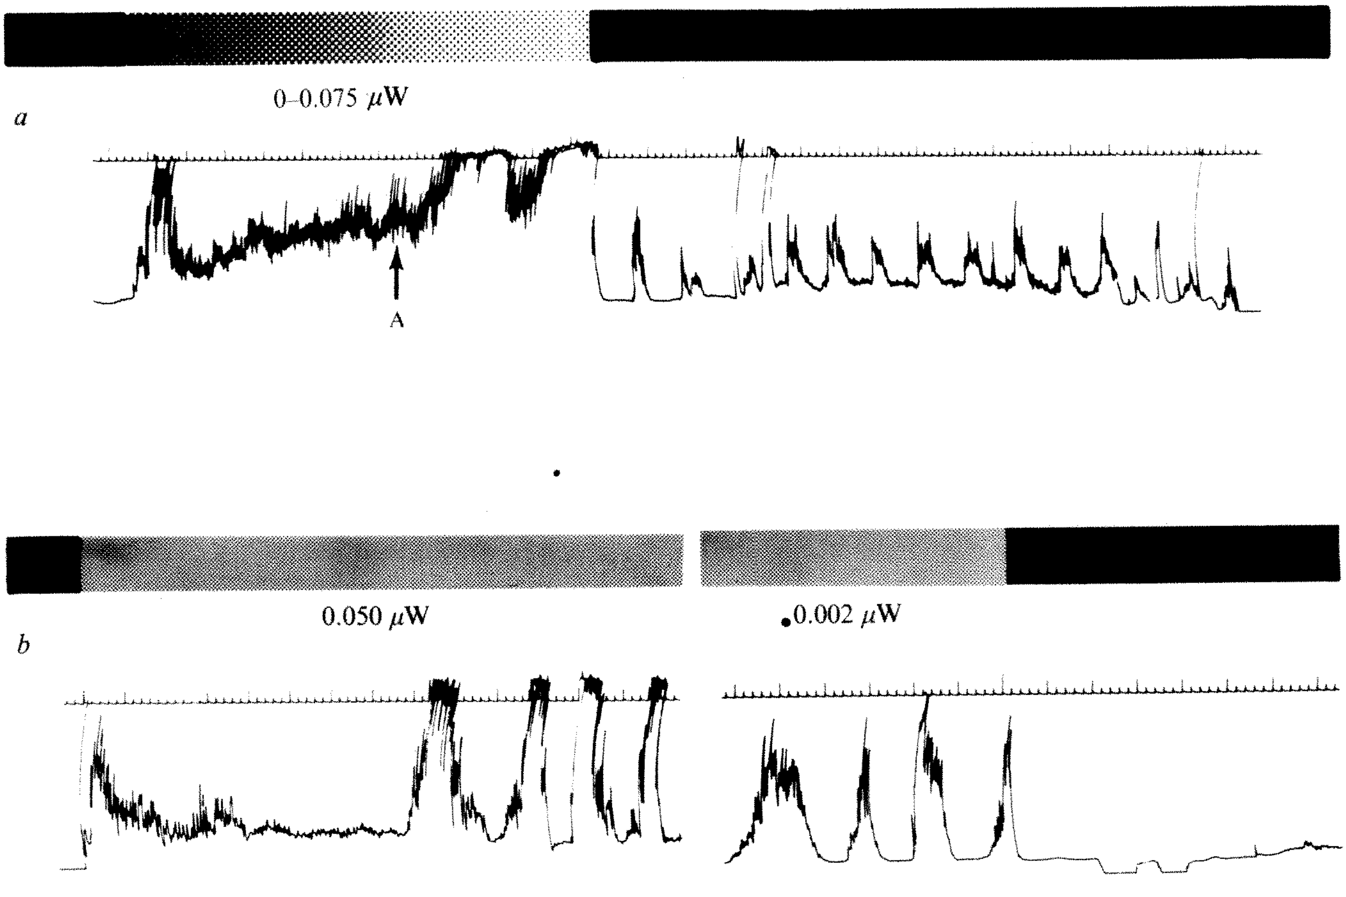

Fig. 1 Photomultiplier recordings of *Symbolophorus* bioluminescent responses to variation in background illumination. *a*, Probable alarm response and gradually increased bioluminescence in response to gradual increase in background illuminance, followed by diminished bioluminescence in darkness (point A equals 2×10^{-5} μW cm^{-2} at photomultiplier); *b*, probable alarm response followed by delayed onset of presumed countershading bioluminescence on sudden increase in background illuminance; *c*, sudden cessation of luminescence on cessation of low-level illumination. Records (*b*) and (*c*) were made with the same specimen. Time marks at 1 and 5 s, increasing bioluminescence indicated by upward deflection of traces.

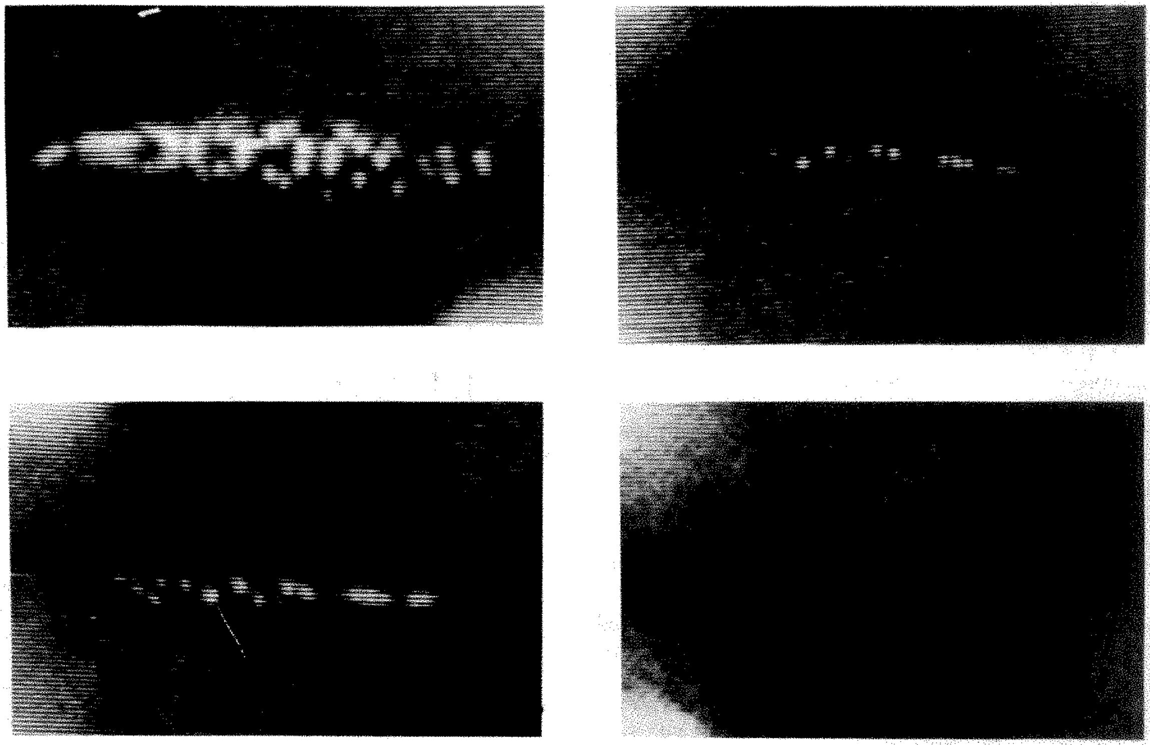

Fig. 2 Image intensified video recordings showing rapid onset of luminescence from ventral photophores of an approximately 5-cm standard length, unidentified myctophid. Interval between first and third frames is 116 ms, 676 ms for the entire series.

During continuous background exposure, bioluminescence continues for at least 15 min, our longest test at a single background irradiance level. The short term peaks (roughly six to eight per min) coincide with the ship's motion. We believe they represent rotation of the free-swimming specimen with reference to the photomultiplier and that bioluminescence during exposure to light is uniform. A similar effect can be produced with an artificial light source in place of the fish. Photomultiplier records (Fig. 1*a*) and visual observations show some low level bioluminescence in darkness, often due only to the slow winking on and off of a single photophore.

Behaviournally-induced photophore responses of myctophids may be more rapid than the 0.5 s measured with the relatively poor time resolution of our recording system, as suggested in image intensified video recordings made according to the method of Barnes and Case[4]. Figure 2 shows video frames of an unidentified myctophid obtained by trawling in the Banda Sea. Within 677 ms all photophores in view have markedly increased their output.

These experiments demonstrate the presence of the requisite visual sensitivity linked with photophore control to facilitate bioluminescent reduction of the silhouette (countershading or counterillumination) in the typical light regime of lantern fish. Both the rapidity of photophore control and the demonstration of what may be a transient alarm response, however, argue that myctophid photophores have other roles.

Voltage signal of photoreceptors at visual threshold

IT has long been known that vertebrate photoreceptors can signal the absorption of single quanta of light[1]. The extraordinary sensitivity of the visual system is usually ascribed both to the sensitivity of the photoreceptors and to the integration of their signals by higher-order neurones. A more complete explanation of visual sensitivity could be given if it were possible to record the response of receptors at the visual threshold. Unfortunately, it has not been possible to do this at the absolute threshold, largely because of interactions between receptors[2]. Near the absolute threshold only a small proportion of the receptors absorb quanta, but the photocurrent from these cells spreads through electronic synapses[3] to many other cells. Thus the voltage responses in the receptors are non-uniform, and it is not possible to tell which responses contribute to the threshold. Fortunately this difficulty does not arise at the increment threshold since in the presence of bright background light, the variation in response from one receptor to the next is minimal. The differences among the receptors in the number of quanta caught will be much less important than at absolute threshold, and the connections between the receptors will tend to equalise their voltages. In this report we compare receptor responses to behavioural responses in the light-adapted turtle and show that the receptor response at threshold is only a few microvolts in amplitude.

The amplitude of turtle receptor responses to flashes of light in the presence of bright backgrounds can be estimated from the results of Baylor and Hodgkin[4]. The sensitivity of red-sensitive cones in the turtle *Pseudemys scripta elegans* varies with the intensity of background light according to the relation

$$\frac{1}{S_F} = \frac{1}{S_F^D} + \zeta I_B \qquad (1)$$

where S_F is the sensitivity of the cones to brief, increment flashes, S_F^D is the cone sensitivity in the dark (that is, with no background light), I_B is the intensity of the background, and ζ is a parameter having the nearly constant value of 20 s V^{-1} per flash. Near threshold the peak amplitude of the receptor response is equal to the product of the increment flash intensity and S_F, the flash sensitivity[4-6]. Thus the voltage signal (ΔV_T) at the increment threshold (ΔI_T) is given by

$$\Delta V_T = S_F \Delta I_T \tag{2}$$

As long as ΔV_T is invariant with background intensity, equations (1) and (2) can be combined to give the Weber-Fechner relation for the behavioral threshold

$$\Delta I_T = k(I_B + I_0) \tag{3}$$

with I_0 equal to $\Delta V_T / k S_F^D$ and the Weber fraction, k, equal to $\Delta V_T \zeta$. Since turtle vision has been shown to obey the Weber–Fechner relation[7,8], a determination of k can be combined with the previously determined value for ζ to give an estimate of ΔV_T.

To estimate the amplitude of ΔV_T, we have measured increment thresholds for *Pseudemys scripta elegans*, the same species of turtle used by Baylor and Hodgkin[4,5]. The apparatus has been described previously[9], but there are some alterations to be noted. The test target consisted of a circular piece of milk glass 4.9 mm in diameter, illuminated by tungsten light from a d.c. source. The test target subtended a visual field of 2°21′ and produced an image diameter size of nearly 300 μm on the retina, as estimated from a schematic eye developed for this animal by D. P. M. Northmore (personal communication). The unattenuated intensity of the white test light was measured with a calibrated thermopile to be 13.0 W m^{-2}. Background light was afforded by a second lamp similar to the test lamp mounted outside the rear of the chamber, whose unattenuated intensity was 177.5 W m^{-2}.

The procedure required a head withdrawal response in order to avoid electric shock. The experimental sequence was under programmed control, and details of training and testing have been reported previously[9]. Stimuli were presented at one minute intervals against a dark background and backgrounds of varying intensity levels. Thresholds were determined by a tracking method such that a response on any trial caused the next stimulus to be reduced in intensity by 0.1 logarithmic unit, and the absence of response caused a like increase in intensity. Determined thresholds were very reliable: The calculated mean 95% confidence interval over the series of thresholds collected was only ± 0.08 logarithmic unit.

The results of the increment threshold measurements are shown in Fig. 1. The data have been fitted with equation (3), using a value for k of 10^{-4} s per flash. Since in light-adapted *Pseudemys* the spectral sensitivity of the behavioural response which we have used for our measurements is in close agreement with the spectral sensitivity of the red-sensitive cones[5,9] we will assume that the curve in Fig. 1 reflects primarily the activity of the long-wavelength cone system. It is doubtful that green- or blue-sensitive cones contributed to our measurements, since the white light of the test and adapting beams had most of its energy in the red region of the spectrum. In any case, small contributions from green-sensitive cones would not affect the calculation of ΔV_T, since ζ is approximately the same for both green- and red-sensitive receptors[4].

From the values of k and ζ, we calculate that ΔV_T is approximately 5 μV. Although there is some variability in our measurements, we estimate that this value is accurate to within 0.3 log unit, so that ΔV_T is at most 10 μV. There are several reasons to believe that this value is an upper limit for the threshold signal. First, the target used in the behavioural measurements was larger than that used by Baylor and Hodgkin[4] and probably produced significant responses in horizontal cells[10]. Horizontal cells in turtle inhibit cones[11], and it is possible that this inhibition was large enough in the behavioural measurements to increase k, thus overestimating ΔV_T. Second, we do not know that our test target was optimum for eliciting responses from turtles. Finally, the intracellular measurements of cone responses were most probably made in the nuclear region of the cell body. The voltage in the synaptic pedicle is probably somewhat smaller.

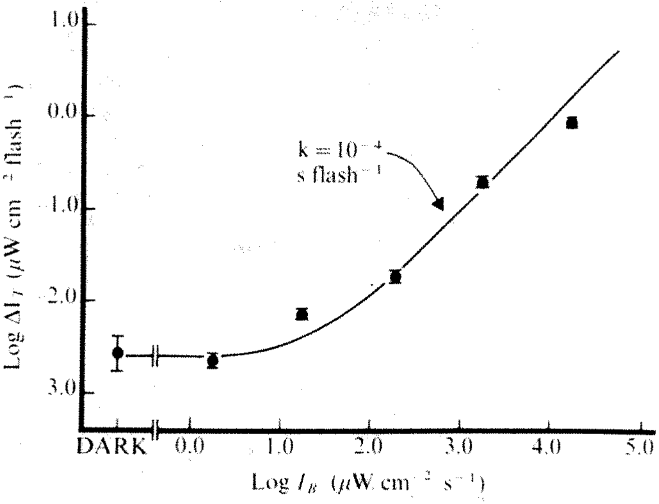

Fig. 1 Increment-threshold curve for the behavioural response of the turtle, *Pseudemys scripta elegans*. Thresholds measured with flashes between 10 and 50 ms have been corrected for the difference in flash lengths and averaged together, since the behavioural threshold in turtle shows complete temporal summation for flashes up to at least that level (Granda and Maxwell, unpublished data). Data points give the mean threshold and bars, one standard deviation. Points have been fitted with equation (3) using a value for k of 10^{-4} s per flash.

Our results show that a receptor response of no more than 10 μV is sufficient to signal visual detection. This means that a very small voltage can change the flow of synaptic transmitter between receptors and second-order neurones, suggesting that the sensitivity of transmission at the receptor synapse makes an important contribution to the sensitivity of photodetection. It is of some interest that the threshold signal in photoreceptors appears to be comparable in magnitude to the signals estimated to produce threshold responses in electroreceptors[12]. Both photoreceptors and electroreceptors make synapses with second-order neurones which are characterized by presynaptic specializations including a synaptic ribbon or bar and an arciform or presynaptic density[13] which may function to direct the release of synaptic transmitter[14,15]. The similarity in the microanatomy of the synapses in these two systems suggests that the characteristic presynaptic specialisation at receptor synapses may serve to permit the signalling of small amplitude responses.

Unusual resistance to ultraviolet light in dark phase of blue-green bacterium *Anacystis nidulans*

THE role of visible light in the repair of ultraviolet light-induced damage has been extensively studied in various organisms[1]. In blue-green bacteria, photoreactivation has been found to be extremely efficient[2]. Indeed, in these organisms, which generally need light as a growth factor, the presence of an efficient photoreactivation mechanism hinders the detection of alternative repair steps which may be present. In spite of this difficulty, however, the existence of light-independent (that is, dark) repair has been observed in blue-green bacteria as suggested by the isolation of mutants with altered ultraviolet light sensitivity[3,4]. Here we report an interesting observation suggesting the presence of a very efficient repair system against damage induced by ultraviolet light (254 nm) in an obligate photoautotrophic blue-green bacterium *Anacystis nidulans*. We show that this repair system is either inhibited or less effective under aerobic conditions in the presence of light.

Synthetic medium, C-Mn, both for liquid and agar plate, was used for growth of *Anacystis nidulans* as described by Van Baalen[5]. Liquid cultures were grown at 36 ± 0.5 °C in a water bath shaker and at a light intensity of 200 foot candles from tungsten lamps. In the exponential phase, the doubling time under these conditions of growth was 5 h. Agar plates with cells spread by glass rod were incubated in tungsten light at an intensity of 200 ± 10 ft cd and at 35 ± 1 °C for 5 to 6 d after which colony counts were taken. Under these conditions of growth 100% plating efficiency was obtained.

Cells preincubated in the dark acquired a high resistance to ultraviolet light as compared to cells kept in the light (Fig. 1). This was observable in conditions when the repair by photoreactivation was reduced to minimum. It has been shown that after about 18 h of dark incubation following ultraviolet light exposure no significant change in survival can be effected by photoreactivating light, indicating the presence of only insignificant photoreactivable damage[4]. In order to minimise the repair by photoreactivation, we therefore maintained 24 h of post-exposure dark incubation at room temperature (25 °C). Since photorespiration is blocked in dark incubated cells we thought it would be interesting to see if blocking the total respiration could change the sensitivity[6]. Indeed, when the cells were incubated in light in anaerobic conditions (that is, in an argon atmosphere), the ultraviolet resistance was restored considerably in them (Fig. 1, curve *L*₁).

Significant metabolic differences have been found to occur in light and dark phases of *Anacystis nidulans*. In their studies on macromolecular synthesis, Hayashi *et al.* showed that all species of RNA synthesis continued for at least 4 h in the dark in contrast to DNA synthesis which is stopped in the dark[7]. It is also interesting to note that in the dark this organism accumulates relatively larger amounts of two stable RNA species whose biological functions are still unknown[8]. These are also synthesised in the illuminated cells but are unstable in them. We have observed that when dark incubated cells are transferred to light the ultraviolet resistance is lost in about 1 h, a period within which these stable RNA species have been reported to disappear in light[8]. We have also observed that dark incubated cells when exposed to visible light immediately after ultraviolet light treatment are more sensitive than those not receiving the visible light exposure. This dose of visible light, however, causes the recovery of a very significant fraction of cells exposed to ultraviolet light which are preincubated in light in aerobic conditions and are extremely sensitive to ultraviolet light (our unpublished data). In view of these

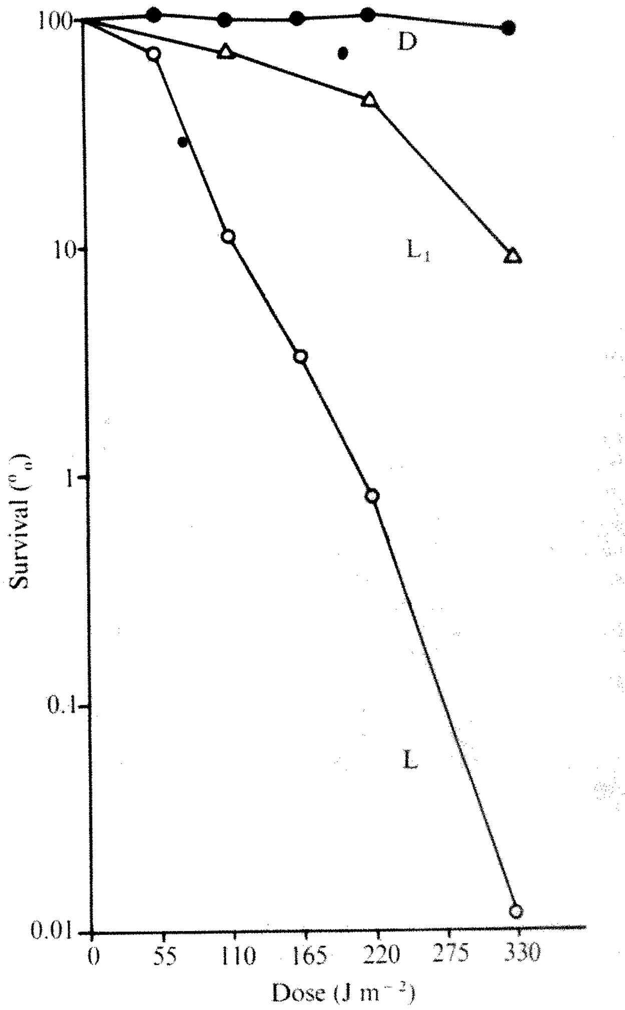

Fig. 1 Survival by *Anacystis nidulans* of exposure to ultraviolet light. Exponential phase cultures of *Anacystis nidulans* were washed with nitrate-free C-Mn medium and resuspended in the same medium at 10^7 – 10^8 cells ml^{-1}. The suspension was divided into three fractions. One fraction was kept in the dark by covering the flask with aluminium foil (D). The second fraction was kept in a vial with rubber cap, sealed with wax and was sparged with argon gas for 30 min (L_1). The third fraction was kept in an uncovered flask (L). All the samples were transferred within 40 min of washing to a water bath shaker at 36 ± 0.5 °C. L and L_1 received tungsten light at an intensity of 200 foot candles. After 24 h of incubation the cells from L, L_1 and D samples were diluted appropriately in C-Mn nitrate-free medium and spread on synthetic agar plates with a sterile glass rod under dim light. Plates with cells were exposed to ultraviolet light (254 nm) from Philips TUV 15 W germicidal lamp at an intensity of 11 J m^{-2} s^{-1} as measured by an Eppley 12 junction linear thermopile. The control and the treated plates were kept in the dark for 24 h at room temperature (25 °C). After the dark incubation all the plates were transferred to light (200 ± 10 ft cd) at 35 ± 1 °C. At the end of incubation in light for 5–6 d the colony counts were taken.

observations we suggest the existence of certain repair steps which are either more efficient in the dark or inhibited in the light under aerobic condition prior to ultraviolet light exposure. The possibility that this differential ultraviolet light sensitivity is due to differences in the nature and extent of primary damage in the light- and dark-incubated cells cannot be totally ruled out by these observations. That this effect is due to the DNA replication inhibition in the dark incubated cells seems improbable. This is because in our experiments both light- and dark-incubated cells were suspended in a nitrate-free medium for 24 h before ultraviolet light exposure. *Anacystis nidulans*, not being a nitrogen-fixing organism, does not grow in the absence of nitrate.

The presence of any repair system against damage induced by ultraviolet light which may either be induced in the dark or inhibited in light is not known. The reverse has, however, been reported. It has been shown that a large, free-living protozoan *Amoeba proteus*, grown in the dark, acquires sensitivity in its G_2 phase to near ultraviolet (365 nm) light as compared with cells cultured in 12 h light/12 h dark cycle[9]. Resistance is restored in dark-grown cells within 10 d of transfer to light/dark cycle. It has also been shown that the *Nicotiana tabacum* plant kept in dark for 7 d lose their capacity to photoreactivate tobaco mosaic virus RNA treated with ultraviolet light[10]. This capacity can be restored by transferring the plant to light.

We thank Dr S. Chatterjee for his suggestions and for going through the manuscript. We thank Dr J. Thomas for supplying *Anacystis nidulans.*

Evidence for nuclear antigens in cytomegalovirus-transformed human cells

THE anti-complement immunofluorescence (ACIF) method has revealed an antigen localised in the nucleus of both producer and nonproducer cultures of lymphoblastoid cells carrying the Epstein–Barr virus (EBV) genome[1]. Early nuclear antigens resembling the Epstein–Barr nuclear antigen (EBNA) have been detected in human embryo lung (HEL) cells as early as 3 h after infection with human cytomegalovirus (CMV)[2]. These early antigens could be detected only by ACIF staining. We have reported[3] that hamster embryo fibroblasts (HEF) transformed with ultraviolet-inactivated CMV exhibit cytoplasmic and perinuclear CMV-specific antigens when tested with CMV-immune sera in the indirect immunofluorescence (IF) test. We later noted that a human CMV of genital origin established a long-term persistent infection in HEL cells *in vitro*, which resulted in the development of two transformed cell lines after several cell culture passages[4]. CMV-specific antigens were demonstrated on the surface of the cells by the indirect IF technique. We have now investigated whether EBNA-like nuclear antigens can be detected in the CMV-transformed human cells with the ACIF technique, and whether there is a correlation of reactivity with early antigens of CMV-infected cells.

Monolayers of HEL cells were grown on coverslips in Dulbecco's medium supplemented with 10% foetal calf serum. The CVM-transformed human cell lines CMV-Mj-HEL-1 and CMV-Mj-HEL-2 and the tumour cell line CMV-Mj-HEL-2, T-1 were established as before (ref. 4 and our unpublished work with J. Kreider). These cells were grown on coverslips in Ham's medium supplemented with 20% foetal calf serum, 0.075% sodium bicarbonate, penicillin (100 IU ml^{-1}) and streptomycin (100 μm ml^{-1}). The C-87 strain of CMV was used for the inoculation of HEL cells at a multiplicity of 0.3 plaque-forming units (PFU) per cell. Cell sheets were fixed 3, 6 and 48 h after inoculation as described before[2]. As a control, the HIL strain of herpes simplex virus type 1 (HSV-1) and the 333 strain of herpes simplex virus type 2 (HSV-2) were used at a multiplicity of infection of 6.0 PFU per cell. Cell sheets were fixed with acetone-methanol 6 h after infection.

Human sera were obtained from hospital patients and staff members of our department. Sera of patients with CMV mononucleosis were supplied by Dr W. Henle of Children's Hospital, Philadelphia. HSV-2-specific hamster serum had an IF antibody titre to HSV-2-infected cells of 1 : 32.

HEL cells, CMV-infected HEL cells or CMV-Mj-HEL-1 cells (10^8 per ml) were used for the adsorption of the sera. Cells were added to undiluted sera, sonicated and incubated for 1 h at 37 °C and then overnight at 4 °C. The cell debris was removed by high-speed centrifugation.

Anti-human and anti-hamster immunoglobulin G fluorescent conjugate (goat) and fluorescent conjugates for anti-human complement staining (goat) were purchased from Cappel Laboratories, Downingtown, Pennsylvania. Fluorescein isothiocyanate conjugates were adsorbed with 10^8 target cells per ml before use. CMV-negative and HSV-negative human sera were used as the source of complement in the ACIF tests. Standard procedures[2] were used for IF and ACIF tests.

The following results were obtained. Eight of thirteen CMV-immune human sera reacted with nuclear antigens of CMV-Mj-HEL-1 cells. Depending on the immune serum used, 6–80% of the cells demonstrated nuclear antigens (Table 1). The reaction observed was intense and located entirely within the nuclei (Fig. 1*a*). The intensity varied from test to test and among cells within a test, and thus may have depended on the stage of the cell cycle. Occasionally, faint nuclear fluorescence was detected in transformed cells stained by the indirect IF method (Fig. 1*b*), where a more granular pattern was observed. The immune serum did not react with control HEL cells. The CMV-negative human serum, which was the source of the complement in these tests, did not react with the transformed cells (Fig. 1*c*).

There was a correlation between the CMV antibody titre of the immune sera and their reactivity with the nuclear antigens; CMV-negative human sera did not react with the nuclei of the CMV-transformed cells (Table 1). All immune sera with antibody titre higher than 1 : 64 against CMV-infected cells reacted with nuclear antigens of the transformed cells (Table 1). None of the nuclear-antigen-reactive sera reacted with nuclear antigens of control HEL or bladder cancer cells (Table 1). The antibodies to the nuclear antigens of CMV-transformed cells sometimes seemed to develop in the convalescent phase of the infection in some

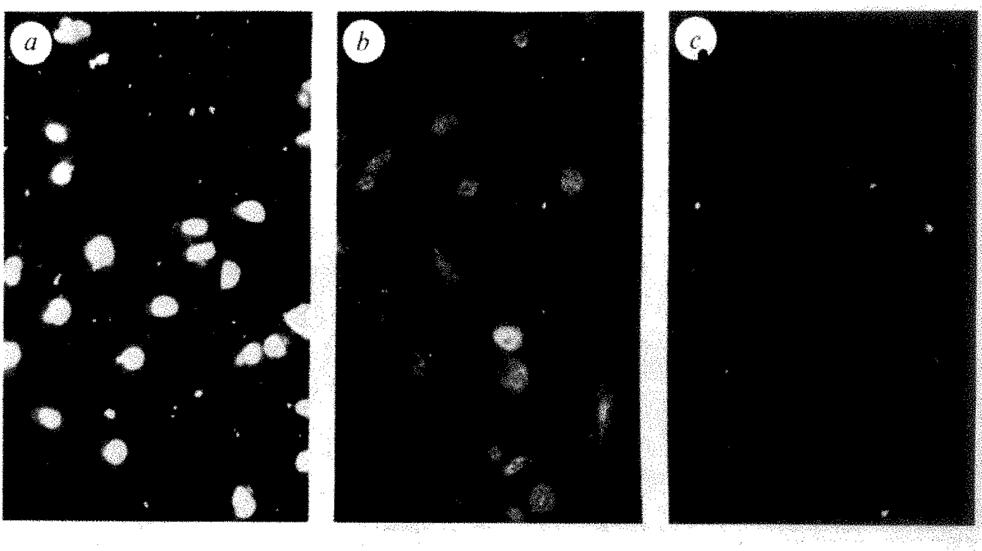

Fig. 1 *a*, Nuclear antigens in CMV-Mj-HEL-1 cells. CMV-immune human convalescent serum was used with human complement and fluorescein isothiocyanate-conjugated anti-human complement goat serum in an ACIF test. *b*, Nuclear antigens in CMV-Mj-HEL-1 cells after reaction with CMV-specific human convalescent serum and fluorescein isothiocyanate-conjugated goat anti-human immunoglobulin G. Note faint staining of antigens with the indirect IF method. *c*, CMV-Mj-HEL-1 cells were reacted with negative human serum used as a source of complement and fluorescein isothiocyanate-conjugated anti-human complement goat serum in an ACIF test (×500).

cases of CMV mononucleosis (Table 1, see sera 2 and 3). All sera that reacted with the nuclear antigens of the transformed cells also reacted with the early (6-h) antigens of CMV-infected cells. Only eight of 13 'early-antigen-reactive' immune sera, however, reacted with nuclear formed cells in the ACIF test.

Adsorption of serum with uninfected HEL cells did not influence the reactivity of the serum with the nuclear antigens of CMV-transformed cells or CMV-infected HEL cells. When adsorbed with CMV-infected HEL cells, however, the immune serum lost its reactivity against the nuclei of transformed and virus-infected cells. The reactivity with HSV-infected cells was not influenced. The adsorption of the CMV-immune serum with the CMV-transformed human cells removed the reactivity with the "early" antigens of the CMV-infected HEL cells and decreased the reactivity with the CMV-infected cells fixed 48 h after infection. HSV-2-immune hamster serum did not react with the nuclear antigens. Sera that were positive for EBNA did not react with CMV-infected or CMV-transformed cells in the ACIF test.

Some of the immune sera reacted with both nuclear and perinuclear antigens, or with only nuclear or perinuclear antigens in the transformed cells. The perinuclear reaction requires further study.

Thus intranuclear CMV-related antigens have been demonstrated in CMV-transformed human cells by means of the sensitive ACIF method. The staining of the nuclei of the transformed cells by ACIF correlated with the presence in the sera of CMV antibodies against late-phase intracellular and 'early' intranuclear antigens of CMV-infected cells. Not all immune sera with anti-CMV antibodies, however, reacted with the transformed cells. This is not surprising in view of the numerous CMV antigens that may elicit the immune response in man. The nuclear reactivity seems to be possessed primarily by immune sera, taken from patients with prostatic cancer or those in the convalescent phase of an acute CMV infection, with a CMV antibody titre higher than 1 : 64 as measured by the direct IF test. There is apparently a relationship between the nuclear antigens of the transformed cells and the 'early' 6-h nuclear antigens of CMV-infected cells. Thus, the nuclear antigens of the transformed cells may be CMV-specific T antigens of CMV-transformed human cells and may be important in immunological studies of the role of CMV in human malignancies. This study was supported

Table 1 Reactions of CMV-positive and CMV-negative human sera to ACIF* tests with antigens of CMV-infected and CMV-transformed cells

Radiation-induced nondisjunction in oocytes of aged mice

SOME human epidemiological studies[1–4] suggest that there may be an association between nondisjunction and preconception exposure to abdominal X rays in women. This response to radiation appears to increase with age[2,4]. To test this hypothesis, experimental evidence was sought by examining second metaphase chromosomes of cultured oocytes of mice. In the previous experiment[5], abnormal segregation was induced in young mice, aged 3–6 months, by exposing them to a low dose of whole body gamma irradiation from a ^{137}Cs source. We have now found that radiosensitivity increases with age.

Virgin female (C$_3$H×ICR/Swiss)F$_1$ hybrids, similar to those used in the previous experiment, were irradiated at age 12 months and killed within a week of exposure. The same proceedure as before was followed for irradiating the females and handling controls. As before, there was no exposure to gonadotrophic hormones and the radiation dose (10–30 R) was kept low to minimise chromosome breakage. The details for obtaining second metaphase chromosome preparations have been described before[5]. Oocytes were placed on a slide and all were accounted for during the analyses. All slides were coded to avoid bias.

After analysis of the preparations by Giemsa staining, coverslips were removed by holding the slides under warm running tap water. The preparations were then air dried. C-banding, not used in the previous experiment, was used when the chromosome count was doubtful. The method of Arrighi and Hsu[6], with modifications suggested by C. E. Ford and E. P. Evans, was used. The dry slides were incubated at 70 °C overnight, placed in warm 2× SSC (0.3 M NaCl and 0.03 M Na citrate) and returned to the incubator for 90 min. They were then stained for 3–5 min in 1 : 20 Giemsa-phosphate buffer, *p*H 6.8, rinsed with fresh buffer and air dried. The best results were obtained when the slides were 1–2 weeks old.

Because of the age of the animals, 2.5 times as many females were required in the second experiment as in the first in order to obtain sufficient oocytes in second metaphase. There was an average of 11 eggs per mouse. Of the oocytes collected 39% proceeded into metaphase II (Table 1). Young females had an average of 36 eggs each, with 25% proceeding into metaphase II. The increased proportion of aged cells in metaphase II is highly significant ($P<0.0001$). On the other hand, significantly more oocytes of young mice remained in metaphase I ($P<0.0001$). Because the oocytes were teased out of the ovaries, these differences probably reflect variations in age of the cells collected. In young mice there is probably a wider distribution of oocytes between early and late dictyotene which could affect the timing of *in vitro* division. Moreover, as a mouse ages the less hardy oocytes may have degenerated *in vivo*.

Table 1 Frequencies of oocytes collected in first metaphase and second metaphase after 18–23 h *in vitro* culture

	Irradiated					Non-irradiated				
	Total	MI	MII	Other stages	Degenerated, no response	Total	MI	MII	Other stages	Degenerated, no response
Aged mice	5,957	430(7.2)	2,269(38.1)	25(0.4)	3,233(54.3)	6,207	399(6.4)	2,518(40.6)	36(0.6)	3,254(52.4)
Young mice	8,046	789(9.8)	2,064(25.7)	34(0.4)	5,159(64.1)	7,667	889(11.6)	1,866(24.3)	24(0.3)	4,888(63.8)
Total	14,003	1,219(8.7)	4,333(30.9)	59(0.4)	8,392(60.0)	13,874	1,288(9.3)	4,384(31.6)	60(0.4)	8,142(58.7)

MI, metaphase I; MII metaphase 2. Figures in parentheses are percentages.

Comparisons between the frequencies of hyperhaploid cells in young and aged mice are shown in Table 2. Hyperhaploidy occurred in irradiated samples at a significantly higher frequency than in controls. When ageing alone is considered, frequencies of nondisjunctional events increased with age, but the increases were not significant for either irradiated or non-irradiated mice. When these numbers are doubled as an estimate of the complementary hypohaploid cells, all comparisons are highly significant. The incidence of nondisjunction among aged controls was 0.6%, increasing to 2.7% on irradiation. The nondisjunction rate for irradiated young females was 1%.

Table 2 Frequencies of numerical aberrations in second meiotic metaphase oocytes of aged mice compared with young mice, irradiated and non-irradiated

		Irradiated (I)				Non-irradiated (C)			
		No. of oocytes analysable	No. of chromosomes			No. of oocytes analysable	No. of chromosomes		
	Dose (R)		19	20	21		19	20	21
Aged mice* (12 months)	10	390	11	370	7	411	16	390	1
	20	376	12	357	5	545	14	524	0
	30	351	18	321	3	350	15	330	3
	Totals	1,117	41	1,048	15	1,306	45	1,244	4
Young mice† (3–6 months)	Totals	1,149	34	1,109	6	1,054	31	1,023	0

For comparison of hyperhaploid cells only—young I against young C, $P = 0.02$; old C against young C, $P = 0.09$ (Fisher exact test); old I against old C, $P < 0.01$; all I against all C, $P < 0.001$; all I against young I, $P < 0.07$; χ^2 with Yates' correction for small numbers).

* Cells with chromatid breaks omitted.

† Details in ref. 1.

Table 3 Frequencies of chromatid breaks and separations

	Dose (R)	Irradiated			Non-irradiated		
		No. analysable	No. with breaks	No. with separations	No. analysable	No. with breaks	No. with separations
Aged mice	10	390	2	15	411	4	27
	20	376	2	25	545	7	21
	30	351	9	12	350	2	19
Totals		1,117	13	52	1,306	13	67
Young mice	10	426	0	2	379	0	5
	20	368	0	3	421	0	2
	30	355	0	11	254	0	2
Totals		1,149	0	16	1,054	0	9

The frequency of chromatid breaks in the oocytes exposed to 30 R (Table 3) was significantly higher than the total number of breaks found in cells exposed to lower doses ($P<0.01$) and in non-irradiated controls ($P<0.03$). Two of these cells had translocations (Fig. 1), and one other chromatid exchange occurred in a cell exposed to 20 R. There were no differences in breakage rates between the controls and cells exposed to 10 R or 20 R. In this sample the critical dose causing a substantial increase in chromatid breaks in the oocytes of aged mice seems to be higher than 20 R. It is difficult, however, to obtain accurate breakage frequencies in metaphase II cells because fragments can be lost during first anaphase. No chromatid breaks were identified in metaphase II chromatids of young females. The frequency of premature chromatid separation was increased in aged mice whether irradiated or not (Table 3). The primary purpose of this experiment, however, was to evaluate the effect of radiation on meiotic chromosome segregation.

Yamamoto *et al.*[7] found spontaneous and induced nondisjunction among the progeny of aged females but not of young mice. Lüning *et al.*[8] examined the effects of low dose X-ray exposure and age of females on the rate of intrauterine death, used as an indication of aneuploid offspring. They found that late maternal age at the time of mating had a considerable effect on foetal death rate but no detectable influence was noted from X-ray exposure with doses of 2–32 R. Reichert *et al.*[9] induced chromosome anomalies with X rays and found nondisjunctional products among second metaphase oocytes of irradiated females and none in controls: the difference, however, was not significant. They did not exclude the possibility that X rays induce abnormal segregation.

Our results with mouse oocyte chromosomes indicate that abnormal segregation may be induced during first meiotic division by *in vivo* exposure of mouse ovaries to low doses of radiation. This radiosensitivity seems to increase with age; the increase in abnormal segregation is more than twice the frequency found in young mice. This evidence in the mouse supports the suggestion that the risk of producing trisomic offspring among humans is increased with exposure of the abdomen to diagnostic X rays. Human radiation response has also been found to be related to late maternal age[3,4]. Examination of the results of 11 epidemiological studies[10] indicates that all but two[11,12] show an increase in nondisjunction with radiation exposure, although in some series these increases were not statistically significant.

We thank Drs C. E. Ford and E. P. Evans for assistance and encouragement. Technical assistance was provided by Heidi Jamro, Belva Sutherland and W. S. Tsuchida. Support was provided by a grant from the Medical Research Council of Canada.

Photo-oxidation of water in phospholipid bilayer membranes containing chlorophyll *a*

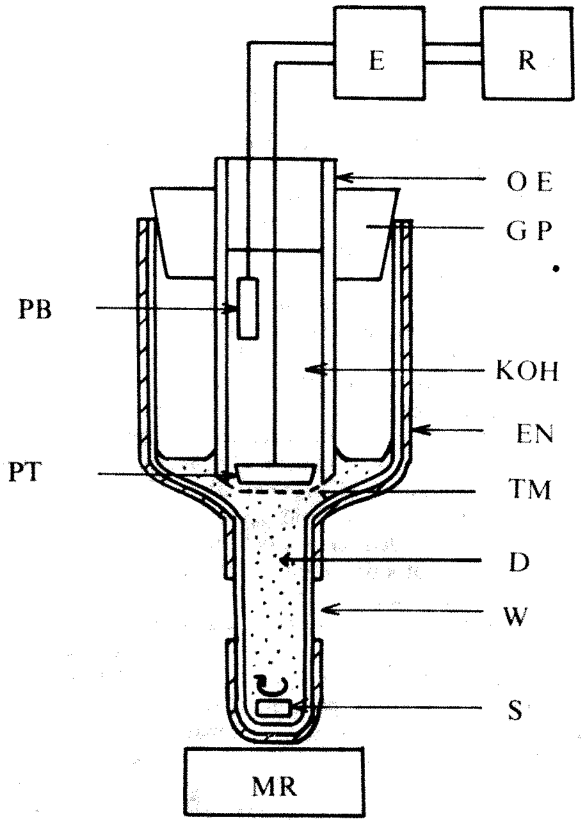
THE process of electron transfer from water to NAD in living photosynthetic systems involves a crystalline or liquid crystalline two-dimensional lattice of chlorophyll and other pigments. We describe here an artificial model system, with one of the characteristics of pigment system II, in which oxidation of water under the influence of red light (680 nm) is mediated by chlorophyll incorporated into bilayer membranes.

There have been several investigations of the photosensitivity of chlorophyll incorporated into phospholipid bilayers. For example, when chloroplast extracts were incorporated into the phospholipid bilayer separating two aqueous solutions of different redox potential, photocurrents through the bilayer were observed[1-3]. A peak was observed at 680 nm, corresponding to the red absorption of chlorophyll *a*[4]. Nicholls *et al.* incorporated chlorophyll a into lipid liposomes and observed the photooxidation of added ferrocytochrome *c*[5], and Tomkiewicz *et al.* observed photoproduction of the chlorophyll *a* cation radical in the presence of the water-soluble oxidants[6]. This suggests that redox reactions take place at the membrane–solution interface under the influence of light absorption by chlorophyll *a*. We report here light-induced oxidation of water in aqueous dispersions of phospholipid liposomes containing chlorophyll *a* and *b* together with small amounts of other pigments within the chloroplasts of spinach leaves.

To confirm that photo-induced oxygen production takes place at one surface of the bilayer membrane and is associated with a redox reaction at the other surface, we used liposome dispersion systems containing water-soluble oxidants only in the aqueous compartment inside each liposome.

A preparation consisting of chlorophyll *a* (68.0 weight %) and *b* (22.8 weight %), and pigments such as carotene and xanthophyll (9.2 weight %) was prepared from spinach leaves by repeated precipitation in a methanol–dioxane–water mixture in the appropriate proportions[7]. Phosphatidylcholine was isolated chromatographically from egg yolk[8]. Liposome dispersions were prepared by suspending colyophilised phosphatidylcholine (100 mg) with a given amount of the chlorophyll preparation and a trace of carbonylcyanide D–trifluoromethoxyphenyl hydrazone (FCCP) in a 5-ml aqueous solution of appropriate composition. The suspension was irradiated ultrasonically with a sonicator at 20 kHz and 4 °C under argon for 15 min. Undispersed phospholipids were removed by centrifugation at 13,000*g* for 10 min. The resulting supernatant was subjected to molecular sieve chromatography at 4 °C on a column of Sepharose 4 B. The elution profile of the dispersion consisted of two distinct peaks. The position of the second peak was independent of the molar ratio of chlorophyll *a* to phosphatidylcholine in our experimental conditions and was similar to that observed for liposome dispersion without chlorophyll. Thus the liposomes in this peak were about 250 Å in diameter[9]. To prepare a system in which oxidants existed only in the aqueous interior of each liposome, sonication was carried out in an aqueous solution of 0.1 M potassium ferricyanide, 0.5 M Tris-chloride and 0.1 M potassium chloride at *p*H 7.50. $K_3Fe(CN)_6$ was removed from the external aqueous phase by rapid passage of the liposome dispersion at 4 °C over a column of Sephadex G-50 which had been equilibrated with the aqueous solution of 0.5 M Tris-chloride and 0.1 M KCl at *p*H 7.50. A sample of 5 ml of the resulting dispersion was transferred to a glass cell with an oxygen electrode connected to a high speed electrometer (417 High Speed Picoammeter, Keithley, Fig. 1). The outside of the cell was coated with a thin layer of black enamel to protect it from stray light, except for a window of 1.2 cm² through which the liposome system was irradiated with light. In particular the oxygen electrode was not exposed to light. Before irradiation with light, the dispersion was bubbled with Ar gas for 20 min to remove dissolved oxygen. A 500-W xenon lamp with an infrared cut off glass filter was used throughout the experiments and light intensity was varied by means of neutral density filters. A monochromator or a set of interference filters was used as needed.

Fig. 1 Schematic diagram of experimental setup for measurement of light-induced oxygen production in the chlorophyll-liposome system. E, electrometer; R, recorder; GP, gum plug; OE, oxygen electrode; KOH, 0.1 M KOH solution; PB, Pb electrode; PT, Pt electrode; TM, Teflon membrane; EN, black enamel layer; D, dispersion of liposomes; W, window; S, stirring bar; MR, rotary magnet.



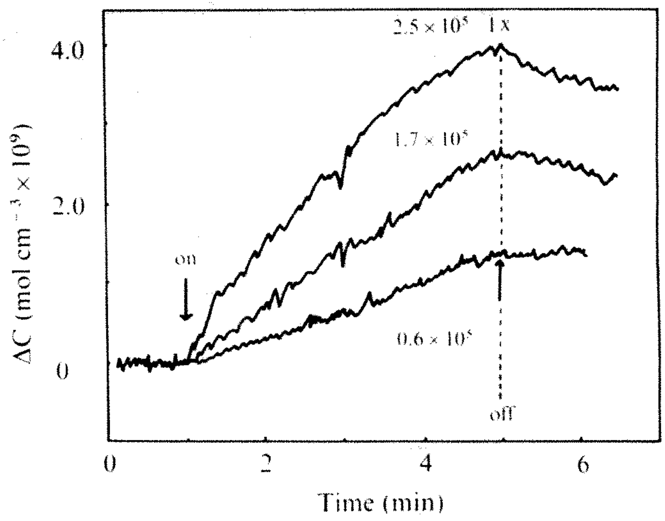


Fig. 2 Change of oxygen concentration in the liposome dispersion when illuminated by white light of three different intensities. Numbers represent light intensity in lx.

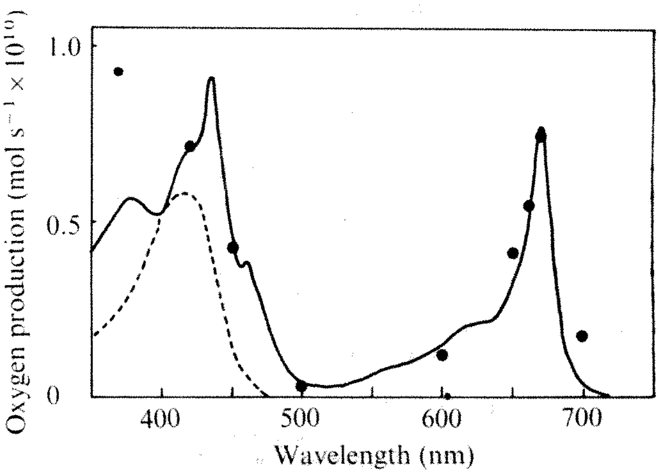
Figure 2 illustrates the change in oxygen concentration in the external aqueous phase under white light illumination at various intensities. The data were obtained in a dispersion of the liposomes composed of 100 mg of phosphatidylcholine and 1.0 mg of chlorophyll preparation. The rate of oxygen production calculated from the initial slope of each line was nearly proportional to the light intensity. The rate of oxygen production at 100,000 lx was 4.2×10^{-11} mol^{-1}. Figure 3 compared the action spectrum of the photoproduction of oxygen in the same system with the absorption spectra of chlorophyll incorporated in the liposome and of $K_3Fe(CN)_6$ in aqueous solution. The position of the red band of chlorophyll *a* in the liposome bilayer was similar to that observed for chlorophyll *a* in ethanol solution. As Fig. 3 shows,

Fig. 3 Comparisons of the action spectrum for oxygen production with the absorption spectra of the chlorophyll sample in the liposome bilayer and of $K_3Fe(CN)_6$ in aqueous solution. ●, Action spectrum for oxygen production; ——, absorption spectrum of the chlorophyll sample in the liposome bilayer; – – –, absorption spectrum of $K_3Fe(CN)_6$ in aqueous solution.



the action spectrum has two peaks around 420 nm and 670 nm, corresponding to the absorption bands of chlorophyll *a* in the liposome bilayer, but has no similarity to the absorption spectrum of $K_3Fe(CN)_6$. These results suggest that the reaction proceeds by utilising photoenergy absorbed by chlorophyll. In the absence of $K_3Fe(CN)_6$ in the compartment of each liposome, oxygen production was scarcely observed even in the light.

Tomkiewicz *et al.* observed the photoproduction of the chlorophyll cation radical in the dispersion of liposomes containing chlorophyll a in the presence but not in the absence of $K_3Fe(CN)_6$ (ref. 6). Taking their results into consideration ours might be expressed

$$\text{chl} + h\nu \longrightarrow \text{chl}^* \quad \text{photo-excitation} \qquad (1)$$

$$\text{chl}_i^* + \text{Fe}^{3+} \longrightarrow \text{chl}_i^+ + \text{Fe}^{2+} \quad \text{chl cation radical formation} \qquad (2)$$

$$\text{chl}_i^+ + \text{Fe}^{2+} \longrightarrow \text{chl}_i + \text{Fe}^{3+} \quad \text{overall back reaction} \qquad (3)$$

$$\text{chl}_i^+ + \text{chl}_o^* \text{ (or chl}_o) \longrightarrow \text{chl}_i + \text{chl}_o^+ \quad \text{charge transfer} \qquad (4)$$

$$\text{chl}_o^+ + 1/2\,\text{H}_2\text{O} \longrightarrow \text{chl}_o + 1/4\,\text{O}_2 + \text{H}^+ \quad \text{oxygen production} \qquad (5)$$

In these equations, chl* and chl^+ are excited chlorophyll *a* and chlorophyll *a* cation radical, respectively, and Fe^{3+} and Fe^{2+} represent ferricyanide and ferrocyanide ions. Chl_i and chl_o are the chlorophyll *a* molecules localised in membrane surfaces facing the aqueous phase inside each liposome and the ambient aqueous phase outside the liposome, respectively.

The explanation of these equations is as follows. Chlorophyll *a* is excited by light at both membrane–solution interfaces (equation (1)), but chl^+ is produced only inside the liposomes (equation (2)). The back reaction may occur at the internal surface (equation (3)). Competing with this back reaction, charge exchange between chl_i^+ and chl_o^* (or chl_o) might take place through a redox species present in the membrane, such as carotene and xanthophyll[10] (equation (4)). The chl_o^+ thus generated in the outer surface may oxidise water in the external aqueous phase; consequently oxygen is produced in the ambient aqueous phase. The excess negative charge accumulated inside each liposome by the charge exchange between chl_i^+ and chl_o^* (or chl_o) may be compensated by FCCP-mediated proton transport from the external to the internal aqueous solution of the liposomes.

Structure of nosiheptide, a polythiazole-containing antibiotic

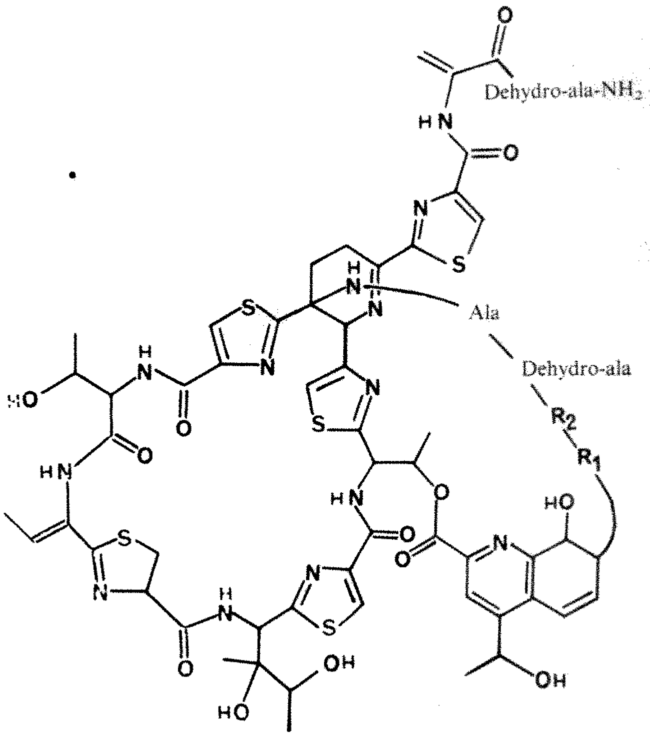
NOSIHEPTIDE is a metabolite with a strong antibiotic action which has been isolated from *Streptomyces actuosus* (F. Benazet *et al.*, unpublished). Studies of its antibiotic spectrum and cross-resistance suggested that it belonged to the thiostrepton family[1]; chemical analyses and further chemical degradation confirmed this view. From analytical and spectroscopic data (NMR ^1H, ^{13}C and ^{15}N) the general formula $C_{51}H_{43}N_{13}O_{12}S_6$ was assigned (A. Brun, H. Depaire, G. Lukacs and J. P. Thomas, unpublished). Unfortunately no M^+ peak can be extracted from its mass spectrum (electron impact). Some parts of the molecule have been identified after degradation by different techniques, namely one L-threonine, one hydroxypyridine, five thiazoles and one indole ring (A. Brun, H. Depaire, G. Lukacs, and J. P. Thomas, unpublished). Nothing could be deduced about the sixth sulphur atom. At least twenty antibiotics are known to contain thiazole rings (for instance bleomycins[2], bacitracin A[2], and althiomycin[3]), but among those containing five thiazole rings only two molecular structures are known: thiostrepton, by X-ray analysis[4] and ^{13}C NMR spectroscopy, and siomycin A, by comparing its NMR spectrum with that of thiostrepton[5]. To obtain the complete structure of nosiheptide, we undertook an X-ray analysis.

Crystals of nosiheptide were grown in a mixture of $CHCl_3$ and C_2H_5OH (3:1) by slow evaporation at 30 °C. Any attempt to change the ratio of the two solvents led to powdery precipitates or unusable small crystals. They were mounted in Lindemann glass capillaries in the presence of solvent which is part of the overall crystal structure, as these crystals decompose as soon as the mother liquor is removed. Crystal data: $C_{51}H_{43}N_{13}O_{12}S_6$, molecular weight = 1,222, tetragonal, space group $I4_1$; $a = b = 36.05$, $c = 11.44$ Å, $Z = 8$ and $V = 14{,}735$ Å^3. (It is noteworthy that thiostrepton, with a similar molecular structure, was first found in the tetragonal system before it was crystallised in the monoclinic form.) A rapid decrease in intensities was found at higher diffraction angles and only 2,740 reflections (spacing limit θ up to 60°) could be collected by a computer-controlled diffractometer using CuKα radiation (filtered by a graphite monochromator) in the $\theta/2\theta$ scanning mode. Intensities were corrected for the effects of slow decomposition and by the Lorentz and polarization factors but not for absorption.

The measured density is 1.41 g cm^{-3}, as in thiostrepton. The calculated density, with eight molecules in the cell, is 1.107 g cm^{-3}. Consequently there is a difference of 336 in total mass of the asymmetric unit which is attributable to the solvent.

Attempts to find the trial structure by the sharpened Patterson method were unsuccessful. The structure was solved with some difficulty by the combined use of the phase function[6]

Fig. 1 Condensed formula for thiostrepton (R_1–R_2 = Ile–Ala) and siomycin A (R_1–R_2 = Val–Dehydro-ala). (From ref. 5.)



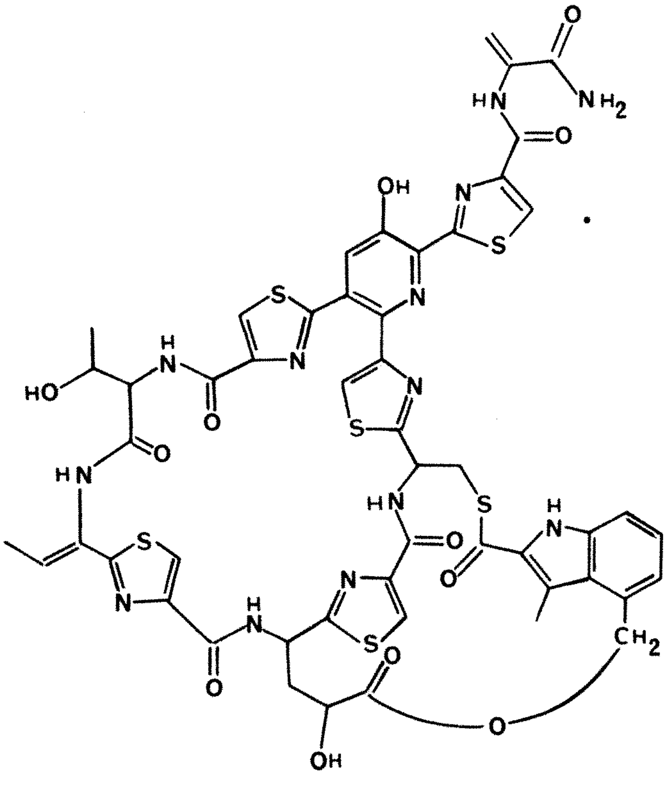
(to select the starting set) and the multisolution method[7] (for tangent refinement). Starting with the four highest peaks of the best E map, regarded as sulphur atoms, a long carbon chain was revealed. A second cycle led to the location of the pyridine ring and the three bonded thiazole rings. Further recycling revealed the complete structure. Identification of the different atoms was made on the basis of chemical evidence (A. Brun, H. Depaire, G. Lukacs and J. P. Thomas, unpublished), temperature factors, bond distances and angles. Details of the crystallographic problems encountered will be published later.

Full matrix least-squares refinement with isotropic temperature factors gave a conventional residual *R* of 25%. The sulphur atoms alone were then assumed to be anisotropically vibrating. Because of the small number of reflections, the rest of the molecule was kept isotropic. The final *R* was 18% with a Cruickshank[8] weighting scheme.

No significant peaks could be recognised in the last difference Fourier synthesis (maximum peak 1 e Å^{-3}) except weak peaks attributed to one $CHCl_3$ molecule with a low occupation factor. The rest of the solvent was therefore assumed to be randomly distributed.

The formula of nosiheptide is shown in Fig. 2 and may be compared with that of thiostrepton (Fig. 1). Some interesting differences are seen: (1) The tetrahydro pyridine cycle (anchorage part of the molecular chains) as well as the thiazoline ring of the thiostrepton backbone, are unsaturated in nosiheptide. Consequently the three chains can be linked to each other in a more planar conformation than the four chains of thiostrepton. Following this observation, the upper part of the molecule is conjugated to the pyridine ring, allowing it to be nearly coplanar, and therefore is much less agitated than the proposed side chain of thiostrepton. The presence of a free hydroxyl group on the pyridine ring might be used to prepare chemical derivatives for further biochemical studies. (2) The quinaldic precursor (quinoline derivative) is replaced by a methylindolic compound of probable similar biosynthetic origin, but differently bridged over the chains. (3) The sixth sulphur atom is found in an unusual thiol-ester linkage. This was rather unexpected on the basis of initial thiostrepton analogies and is, to our knowledge, the first thiol-ester function isolated in an antibiotic compound.

Fig. 2 Nosiheptide, general formula. Chains are attached together by three asymmetric centres which all have the S configuration, deduced from the L-threonine residue.



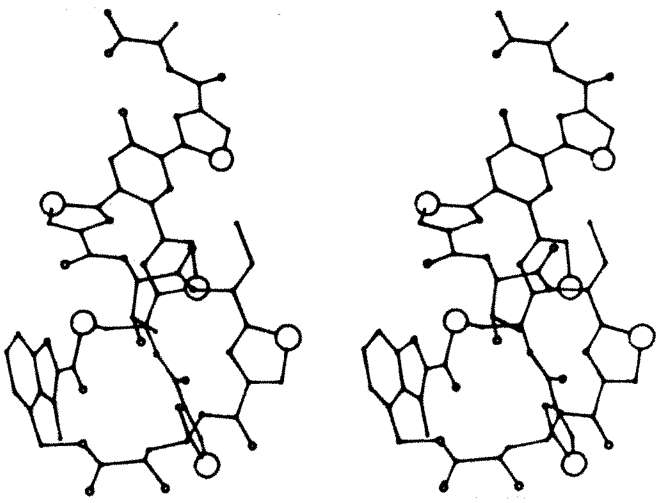


Fig. 3 Stereoscopic view of nosiheptide. The general globular conformation of thiostrepton is very similar, despite the absence of the fourth chain. Drawings of the molecular packing of this structure reveal large void channels in which solvent is in complete disorder.

A stereoscopic view of the molecule is given in Fig. 3 and clearly shows the linkage of the indolic part over the macrocycle constituted by thiazole rings.

Erratum

In the article 'Specific binding sites for oestrogen at the outer surfaces of isolated endometrial cells' by Richard J. Pietras and Clara M. Szego (*Nature*, **265**, 71; 1977), the ordinate labels to Fig. 3 should read from 0 to 80, not from 10 to 90.

The perfect place to stay

The Metropole Hotel Complex is situated inside the grounds of the National Exhibition Centre. Conveniently, it is only a short walk away from the Exhibition Halls and only 20 minutes drive from the heart of Birmingham.

The whole Complex incorporates the five star luxury Metropole Hotel, containing 500 twin bedded air-conditioned rooms and seven luxury penthouse suites, and the adjacent Warwick Hotel with 200 single rooms all with private bathrooms and colour television.

If you would like to make a reservation please complete the attached form and return it as soon as possible.

Entertaining your customers

The Metropole will be pleased to take care of the arrangements for private functions, whether it be a luncheon, cocktail party, buffet, dinner, seminar, business meeting or full scale conference. The variety of intimate bars, spacious lounges, syndicate rooms, lakeside restaurants and recreational amenities combine with the range of exceptional function rooms to make the Metropole a superb venue for entertaining from 20 to 1,200 guests.

WILEY INTERSCIENCE

Electrochemical Stripping Analysis

by **F. Vydra, E. Julaková** and **K. Stulík**, *all of Charles University, Prague.*
Translation editor: **J. Tyson,** *Department of Analytical Chemistry, Imperial College of Science and Technology, University of London.*

This is the first book to present a thorough treatment of all aspects of electrochemical (voltametric) stripping analysis. The method has been applied with great success in trace analysis for monitoring pollutants in food, water, soil and other substances.

085312 017 X 284 pages December 1976
£17.50/$33.25

Published by Ellis Horwood Ltd., Chichester, and distributed by John Wiley & Sons Ltd.

Techniques of Chemistry

edited by **A. Weissberger,**
Vol. 10 Part 1: Applications of Biochemical Systems in Organic Chemistry. Part 2: Applications of Biochemical Systems in Organic Chemistry
edited by **J. B. Jones,** *University of Toronto;* **C. J. Sih and D. Perlman,** *University of Wisconsin.*

Cuts across traditional divisions in chemistry to provide a integrated presentation of the subject. Describes the most recent experimental procedures and incorporates a wealth of other information.

0471 93267 1 536 pages December 1976
Part 1 £24.25/$39.00

£17.50/$29.15

Astronomy Transformed: The Emergence of Radio Astronomy in Britain

by **D. O. Edge,** *University of Edinburgh,* and **M. J. Mulkay,** *University of York.*

Traces the intellectual and technical development of radio astronomy and the accompanying social processes. Illustrates the dynamic interplay between scientific and social factors and shows how the formation of a special network in some countries eventually led to the scientific exploitation of discoveries. (Wiley Series in Science, Culture and Society)

0471 23273 4 500 pages October 1976 £19.25/$31.75

Design and Analysis of Experiments

by **D. C. Montgomery,** *Georgia Institute of Technology.*

This is an introductory textbook dealing with the statistical design and analysis of experiments. The book is intended for readers who have completed a first course in statistical methods and can be used in a second statistics course for undergraduate engineering, physical science, mathematics, biology, and social science students. There are numerical examples illustrating many of the design techniques.

Institutionalised science in America

J. B. Morrell

The Pursuit of Knowledge in the Early American Republic: American Scientific and Learned Societies from Colonial Times to the Civil War. Edited by A. Oleson and S. C. Brown. Pp. xxv+[illegible] (Johns Hopkins: Baltimore and London, July 1976.) £11.55.

In 1769 the American Philosophical Society (Philadelphia), the oldest learned society in the USA, was reorganised into its present form under the presidency of Franklin, who had originally founded it in 1743. Less than a century later, America had produced two national scientific societies: the voluntary American Association for the Advancement of Science (AAAS, founded 1848), and the federally sponsored National Academy of Sciences (founded 1863). After the Civil War both local and national scientific societies were eventually replaced by universities, federal bureaux, specialist societies, and private foundations, as the principal means of discovering, certifying, and diffusing scientific knowledge. Yet in the first hundred years of the American republic, the learned society, devoted to general science, *belles lettres*, technical instruction, agricultural improvement, or the promotion of manufactures, constituted the chief genre of organisation through which knowledge was pursued.

The eighteen papers in this volume were commissioned by the American Academy of Arts and Sciences as the first phase of a collaborative study of the history of institutionalised science and learning in America. By focusing on the scientific centres of the eastern states, such as Philadelphia, Boston, New York and Albany, several contributors confirm the importance of regional differences. The historical significance of local context is, however, best revealed by Shapiro's lively analysis of the Western Academy of Sciences at Cincinnati, the Porkopolis of the mid-West. The theme of scientific knowledge as public utility, conceived patriotically and democratically, is also well covered. Indeed almost all the contributions, which are adequately indexed, deal competently with the staple features of institutional history; and they bristle with dedicated documentation.

By the end of the nineteenth century American science had become 'professional' in several ways: arcane specialisation was rampant; training procedures in laboratories and lecture rooms were well established; qualifications of scientific competence were publicly available and recognised; and many full-time paid jobs in science were filled by certificated individuals. Quite naturally several contributors have been enticed by the theme of professionalisation, the obvious example being Kohlstedt in her account of the ways in which the AAAS reflected and shaped the allegedly professional pattern of the 1850s.

Other authors, however, will have none of this. In a forthright essay Reingold stresses the social and intellectual inclusiveness of most *ante bellum* scientific societies, and accordingly he offers a speculative taxonomy of the scientific community divided into researchers, practitioners, and cultivators. Shapiro's essay erodes the professionalisation model even further by rejecting as unpardonably anachronistic any attempt to divide the membership of American scientific societies into distinct occupations before about 1850.

Irrespective of their attitude to whether professionalisation is a valid organising theme, most contributors present overwhelming evidence to show that many societies failed to fulfil their own stated purposes and that some declined into paralysed, helpless, and hopeless organisations. Especially in a democratic country, where the privilege of learned societies was sometimes suspect, their establishment, maintainance, and growth required the persistent attention of devoted individuals who saved them from precarious existence or quiet extinction. When the continuing existence of so many societies was a pervasive problem, one feels that the professionalisation model is an inappropriate key to their history. Rather one suspects that the origins, purposes, and features of these societies may be interpreted in terms of the various interests, ideas, and resources of the participating and sometimes conflicting members. At least, one would expect that scientific societies faced difficulty in translating aims into action.

For these reasons the most interesting essays are those which deal with failure or which give considerable weight to the aims and perceptions of individual scientists. Hindle, for instance, accounts for the failure of New Yorkers to establish a viable scientific society rivalling those of Philadelphia and Boston by arguing that they preferred to expend their energies in various societies for practical arts modelled on the London Society of Art and not the Royal Society.

Gerstner's analysis of the changing features of the Philadelphia Academy of Natural Sciences reveals the dominance from 1817 to 1840 of William Maclure and the subsequent challenge to it. Sinclair gives similar coherence to his study of the Franklin Institute of Philadelphia by showing how its multifarious activities of the 1820s were redirected by Alexander Dallas Bache into experimental technical research, publication, and public funding. Starting from the assumption that scientific societies only exist when they serve the needs of members as well as those of science, Shapiro shows that in the Cincinnati Academy the unresolved conflicts about classification led to its evanescence in 1854.

Although Kohlstedt employs the professionalisation model, her results reveal the persistent feuding within the early AAAS between the advocates of social inclusiveness led by Henry Darwin Rogers and the elite group of Lazzaroni committed to exclusiveness. Not surprisingly the latter led by Bache became dis-satisfied with the AAAS, and found the highly select National Academy of Sciences far more congenial.

All these contributions confirm that during the past ten years or so American historians have consolidated the history of American science as a lively field, distinguished generally by competence and occasionally by *éclat*. This volume is an admirable testament to that enviable achievement. ☐

J. B. Morrell is a Lecturer in the History of Science at the University of Bradford, UK.

Problems of quantum biochemistry

Quantum Biochemistry and Specific Interactions. By Z. Simon. Pp. 251. (Abacus: Tunbridge Wells, Kent, UK, 1976.) £11.95.

APPLYING the methods of quantum chemistry to problems in biochemistry is so fraught with difficulties that high levels of scepticism are required in addition to enthusiasm for the subject. Until very recently theoretical chemists were not notably successful in calculating properties of small isolated molecules let alone large molecules in aqueous solution or in even more complicated environments.

Over the past few years the problems of molecular physics have become tractable due to refinements of molecular orbital techniques and the power of computers. With the confidence gained from success with the isolated molecule, theoreticians are becoming more interested in biological problems; in particular conformational studies and comparisons of reactivity are proving valuable. Professor Simon's book, originally published in Romanian in 1973, was written before the advances of the past few years, but must have been almost out of date even then.

The molecular orbital technique described in the chapter which follows the introduction is almost totally devoted to π-electron Hückel theory; a final section on 'advanced methods' lists variants more likely to be referred to as 'crude' in current publications; and neither *ab initio* nor PCILO approaches are mentioned. None of the many references cited is later than 1973 despite the fact that the work is described as a 'revised, up-dated translation'. It is an elaboration of the work of the Pullmans in their 1963 book on quantum biochemistry rather than the total revision which would be much welcomed.

Similarly, the chapter on intermolecular forces rests heavily on work by the Pullmans and Scheraga, which both groups would probably consider to have been superseded. Reactivities are discussed in terms of parameters deduced from π-electron calculations rather than the potential surfaces currently in vogue.

The specific interactions referred to in the title and an analysis of some recognition processes occupy the last two chapters of the book. Enzyme reactions, repressor-operator interactions and specificity in immune phenomena are all considered, but much more space is devoted to descriptions of the topics and to quantitative measures than to applications of quantum mechanical methods.

The strength of the book is its collection of facts and topics of biochemistry which remain as problems rather than a description of how they have been solved. The descriptive portion like the theory suffers from the time lag in appearance of the work, but it is impossible to read without feeling an urge to tackle some of the problems with more up-to-date methods.

The book is in no way an account of the state of the art but it is a valuable collection of topics and references more to be recommended to the seasoned campaigner than to the student.

Graham Richards

Graham Richards is a Lecturer in the Department of Physical Chemistry at the University of Oxford, UK.

Whirlpool of aggression

The Evolution and Chemistry of Aggression. By D. D. Thiessen. Pp. xviii+211. (Charles C. Thomas: Springfield, Illinois, 1976.)

THE first chapter of this book is entitled "The Evolution of Competitive Behavior". The other four are on gene organisation, endocrine control, chemical social signals, and the actions of drugs. There is a bibliography of about 300 entries, and a very brief subject index. The author's stated intention is to investigate aggression in relation to evolution and chemistry. "Unless otherwise noted", he writes, "aggression will refer to intermale aggression."

I read the first chapter in some bewilderment. "Aggression," we are told, "in one form or another, is as old as life itself." The first pages include passages on 'molecular aggression', competition between species, predator–prey interactions, and species diversification. There follows a section on "a move toward intraspecific competition" devoted largely to the unusual conduct of a species of sea anemone. There is then one on brain differentiation, in which there are references to 'competitive readjustment of brain size' and 'selection for neurological competence to deal with distance perception'.

Dr Thiessen evidently equates aggression with competition. "If an animal fails to fight", he tells us, "we too readily conclude that he is non-aggressive. . . . Even an animal that does not fight . . . may still be highly competitive." In some passages competition seems to be thought of as equivalent to what goes on in the private sector. The biological principles that deal with competition are those of population genetics, but they are disregarded. Instead, we have tautologies: for example, "there is positive selection for those forms that optimize their use of space and commodities and negative selection for those forms that fail." Similarly, none of the recent critical reviews on natural selection in relation to behaviour, or on intolerant behaviour within species, are represented in the bibliography.

Dr Thiessen's chapter on his own speciality, the endocrine control of behaviour, summarises much interesting work, but again without a unifying theme. Among the many topics mentioned are sex reversal in fish and mammals, the disorganisation of sexual development by early treatment with hormones, the metabolism of the hypothalamus, hormones and social status, and human chromosome abnormalities. There is also a discussion of the behavioural changes that accompany the human menstrual cycle.

Dr Thiessen is not always uncritical. In this field the danger of inferring causal relationships from correlations is always with us. For example, violent prisoners have high plasma testosterone levels. Dr Thiessen remarks that the violence may not be due to the hormone: instead imprisonment could increase testosterone secretion. And on page 82 he utters an important warning: "specialised definitions of aggression involving violence and sexual assault may be more amenable to investigation than more generalised notions of aggression."

This principle could have been usefully applied to the chapter on drugs. "A survey of the literature", we learn, "indicates that almost all classes of drugs studied have been found to decrease, increase or not influence aggression." This is not surprising when we find, a few pages later, a list which includes "footshock aggression" (probably defensive postures induced by pain), "isolation aggression" (possibly a response to strangeness), "irritable aggression" due to brain injury, "aggression" induced by various drugs, and predatory behaviour.

The editor of the American Lecture Series, Dr I. N. Kugelmass, writes in his foreword: "What is aggression? It is life itself—a whirlpool in many ways. When once set agoing it spins on and on." As Australians say, too right.

S. A. Barnett

S. A. Barnett is Professor of Zoology at the Australian National University, Canberra.

obituary

Luigi Gorini, who was a professor emeritus of microbiology and molecular genetics at Harvard Medical School died on August 13 at the age of 72 in Boston. Luigi was born in Milan, in 1903. Although he received his scientific training in the 1920s, he did not really enter his research career until after the second World War. Because he was one of the few scientists who refused to pledge an oath to the fascist government of Italy in the 1930s, he was unable to secure academic employment. He eventually joined the anti-fascist underground.

At the end of the war in Italy, Luigi was a prime mover in establishing a refuge for the many children who were orphaned. Restricted by lack of money and facilities, Luigi decided that the most needy children were Jewish orphans and he set up and ran the home at Selvino for them prior to their emigration to Israel. In 1976, the account of these activities by Luigi and his wife Annamaria Torriani was laid in the Martyrs and Heroes Archives at Yad-Vashem, Israel.

His first scientific paper was published in 1946 when he was 42 years old. Much of Luigi's early work was on the mechanism of protection of various bacterial proteases by ions such as calcium and manganese. He and his coworkers were able to show that the metal ions protected these enzymes against autodigestion by stabilising particular protein conformations. This work had wide impact in that it provided a strong suggestion that proteins do not have unique folding patterns, but can exist in several different stable states.

Upon coming to the United States, Luigi's interests shifted to problems of gene regulation in *Escherichia coli*. In collaboration with Werner Maas at New York University, he used the chemostat to study steady state growth of several arginine auxotrophs with and without arginine. In this way they discovered a large derepression effect on the arginine pathway and were able to show elegantly how repression and feedback inhibition could interact to exert a coarse and fine tuning effect on the rate of enzyme synthesis and arginine formation in that pathway. These studies helped to establish the concept of end-product repression and derepression in biosynthetic pathways. Luigi and his coworkers later continued to contribute to the understanding of regulation of arginine biosynthesis.

After moving to Harvard in 1957, Luigi's research interests expanded to a study of the effect of streptomycin on the translation of messenger RNA into protein. By demonstrating that streptomycin and mutations of the ribosome to streptomycin resistance could influence the accuracy of translation, Gorini and Kataja provided, in 1964, the first evidence that ribosomes were not merely passive templates for protein synthesis. Rather, ribosomes played an important role in determining the interaction between transfer RNA and messenger RNA. These proposals were confirmed directly by *in vitro* experiments in which it was shown that ribosomes sensitive to streptomycin promote mistakes in reading of the code in the presence of streptomycin and other aminoglycoside antibiotics. Subsequently, in 1969, Rosset and Gorini showed that it was possible to increase misreading by the ribosomes through altering a ribosomal protein by the *ram* (ribosomal ambiguity) mutation.

Thus again this large body of work brought Gorini's focus directly on to a basic mechanism for the control of all growth—this time at the level of translation of the gene code. His subsequent work centred around two of the components at this step—the ribosome and transfer RNA. Many of his results in this area were presented in a review on Informational Suppression in 1970 (*A. Rev. Genet.*, **4**, 107–134). His last projects were concerned with establishing an active role for streptomycin with the ribosome or on one of its components, and on the possible interaction of ribosomes in the coupled transcription–translating system.

In 1949, Luigi was awarded the Kronauer Prize by the Faculty of Science at the Sorbonne, and he won the Ledlie Prize of Harvard University in 1965. He was elected a member of the National Academy of Sciences in 1971.

Luigi remained active in his laboratory until the last few months before his death, both advising people in the laboratory and doing experiments himself. One remarkable feature of his scientific life is that, between the time of his official retirement age of 65 at Harvard Medical School and his death, he published 33 papers.

Luigi also remained active politically. He had many letters published in the newspapers protesting policies he opposed. When Henry Kissinger was awarded the Nobel Prize for Peace in 1973, Luigi organised a petition protesting this award. The petition was sent to the Nobel Committee and received publicity in the United States. He also was very active in the anti-Vietnam War movement and spoke out constantly against the use of genetic arguments to support racial discrimination. The following excerpt from a speech he gave in 1970 at Montana State University gives an idea of his conception of the political role of scientists:

> "My job here tonight is to make you realise that for me, like for hundreds of us scientists, my own scientific interest means a lot intellectually but, morally speaking, science alone does not satisfy entirely my conscience. I will try to be the most unequivocal radical possible and at the same time constructive, so that when I quit, your opinion about me should not be similar to that expressed a long time ago by the fascist Italian police about someone whom I know after his first confrontation with them. He was very happy to be released, for a time at least, but a few years later he discovered by chance the written motivation for letting him out and he was really not satisfied. The police file sounds like the following: 'Lonely anarchist; he is not dangerous'."

The following are excerpts from a conversation between the two of us, J. B. who worked in the same department as Luigi, and M. D. who worked in his laboratory.

M.D. Politics probably shared equal prominence in his life with science.

J.B. He would be horrified when people would do things that didn't fit in with his sense of morality. He never lost his sense of outrage.

M.D. Things were black or white to him. In a way it was a great strength of character. He would never compromise.

J.B. Very frequently in the morning he would come rushing down the hall into my office, holding a newspaper or asking me if I'd seen or heard the news that morning. We had to do something right away about it—compose a letter . . .

M.D. . . . or send off a telegram.

J.B. Or sometimes when he got home he had heard something on the news and he was so upset that he would have to call people. I connect his continued sense of outrage about anything political that upset him with his intense enthusiasm and involvement in his scientific work. He never mellowed in that sense.

M.D. He was always in the lab. before anyone else. He was so enthusiastic that he would have got everyone's plates out of the incubator before they came in.

J.B. It seems amazing to me that he maintained that involvement until the end—that it never dissipated.

M.D. He was talking once about a scientist who was retiring and was going to retire to live in Europe. He said "How can a man live like that without science? If I didn't have something to look forward to every day, what would my life be?".

He was not encouraging in that he would say: "That was a really nice experiment". But it was his enthusiasm that was so overwhelming. He tried to have a personal relationship with everyone in the lab. And discussions about projects, although sometimes heated, were usually fruitful, amicable, encouraging and often hilarious.

J.B. He was physically very active. A few years ago he was climbing mountains in the Dominican Republic.

M.D. We went to Mount Washington once, we drove to the top. We climbed down a way and then climbed back up to the car. He was really amazing. He was walking at a good pace, while everyone else was struggling up.

J.B. He was always telling jokes or funny stories. When he entered this country as an immigrant, he had to answer some questions. One of the questions was about adultery. Luigi answered the interviewer by asking "Do you want a yes or no answer or number of times".

M.D. He was such a good teacher to people in the lab. about life and about everything.

Jon Beckwith
Margaret Duncan

John Donald Rose, FRS, who died on October 14 was a former Research and Development Director of Imperial Chemical Industries Ltd. He was born on January 2, 1911 in Rotherham, near Sheffield and went to Rotherham Grammar School before reading chemistry at Jesus College, Oxford. Throughout his life, he never lost a certain bluff "no nonsense" Yorkshire earthiness. He was also a man of quite exceptional kindness and generosity of spirit, and had a well-developed sense of the ludicrous. The combination of these qualities was exceedingly attractive and it was well-nigh impossible not to like "J.D."

He took a First in chemistry at Oxford, and was awarded a Salters' Institute Fellowship, part of which he chose to spend working in Prof. L. Ruzicka's laboratory at the Eidgenössische Technische Hochschule in Zurich. He joined the Research Department of the Dyestuffs Division of ICI at Blackley in 1935 and is believed to have been the first person to make a sample of Nylon 66 in this country, just as he was later to be one of the first ICI men to develop Whinfield's recently discovered polyethylene terephthalate ("Terylene"). During the war he was a member of, and later head of an Exploratory Research Section, and carried out a thorough investigation of the chemistry of the nitroparaffins. At the end of the war, he was deeply involved in the detailed examination of unpublished German war-time research, and his good working knowledge of German made him a valuable interrogator. Characteristically he was kind and generous to German scientists who were being held as possible war criminals. Thereafter, he was rapidly promoted, becoming Research Director of the Dyestuffs Division in 1951.

It was during his term as Research Director that Rattee and Stevens discovered the reactive cotton dyes, the "Procions." J.D. knew very well that the ICI patent position and technological lead were not initially very strong, and he showed great courage in deploying a major effort, fully supported by his colleagues on the Development side, to get the "Procions" on to the market very quickly—in fact within two years. Considerable faith was needed to persuade the dyeing industry to adopt totally new techniques and concepts, but the venture succeeded and the first three dyestuffs were soon expanded into a full range.

In 1959 he was transferred to the Paints Division as joint Managing Director, becoming Chairman in 1964. In 1966 he joined the ICI Board as member responsible for research and development. He was elected Fellow of the Royal Society in 1971 in recognition of "his contributions to chemical science and its utilisation in industry." After his retirement in 1972 he held office as Master of the Salters' Company (1973), an honour which gave him particular pleasure.

It would be wrong to suggest that J.D. was an outstandingly original scientist—he never claimed to be one. His talent was a great clearness of mind, sound judgement and the ability to guide and encourage those associated with him. Many ICI scientists would gladly agree that their own developments or discoveries owe something, often far from negligible, to him.

He died at the age of 65, leaving a widow, son and daughter, and four grandchildren.

M. A. T. Rogers

Dr Alfred E. Emerson, the world famous termitologist died on Sunday October 3, 1976 at Glenn Falls, New York.

He was born in Ithaca and was educated there, at Cornell University. In 1922 he became an Associate Professor in the Department of Zoology at Pittsburgh University, but moved to Chicago in 1929, to remain there for the rest of his academic career, becoming an Emeritus Professor in 1962.

His major research was on the taxonomy of termites, regarded by the uninitiated merely as pests, but to Dr Emerson fascinating social creatures, posessing, as they do, a large measure of self-sacrifice, a trade union system that runs with a minimum of demarcation disputes, and very sophisticated engineering—some termites air-condition their nests by humidity and heat control (sometimes by using the metabolic heat producton of fungi deliberately brought into the nest for the purpose) and by the cunning design of interconnecting air shafts.

In his research he travelled extensively, living on occasion in tribal villages in the remote jungles of Borneo and the Congo, capturing, cataloguing and classifying termites. His collection, built up over half a century of expeditions, comprises of 1,645 species (to Emerson's chagrin, only 93 per cent. of the known world total) and is preserved, pickled in alcohol, in the Museum of Natural History in New York, to whom Emerson presented it in 1964. It has already proved invaluable to termitologists from all over the world. The fascination of the termite world is conveyed by a book *Termite City* which, together with his wife, née Eleanor Fish, he wrote for children.

This was just one of his numerous publications, dealing with his primary research, evolution (he was a proponent of the controversial but now largely discredited theory of the Superorganism) and ecology. He became interested in ecology long before it was fashionable; he was elected president of the Ecological Society of America in 1941, and, amongst the many honours showered on him, was named 'Eminent Ecologist' by them in 1967.

Systems for sale; way of life comes free

For as long as nations have been going to war with each other, capturing the market of another country has been regarded as a desirable alternative to the bloody business of capturing its virgins, chests of gold, galleons or surface-to-air missiles. And whilst a favourable trade balance made up from a portfolio of exports ranging from pins to double-decker buses is a fairly good way of making a possible enemy into an ally out of necessity, a much better way, most governments seem to agree, is by exporting whole systems as opposed to single items.

The virtue of your system in someone else's territory is pretty obvious. First it needs installing: not really a job that the locals can do, so hordes of technicians are temporarily exported to roam unchallenged in the course of their technical duties. Then the locals have to be taught how to keep it going: schools are established and, with luck, some of your own way of life and thinking rubs off, along with all the know-how. Then there will be a continuing demand for spares—available, of course, only from the original manufacturers if the design is made exotic enough. There will be a steady stream of advisers, consultants, conferences and working parties. And when the system wears out, guess who has just the right second-generation system, tailor-made to requirements and ready to start the cycle all over again. It is clearly much more than just foreign exchange which such an arrangement brings in—it provides cultural links, a terrestrial toehold and, of course, political benefits.

In the past these super-exports have included legal systems, constitutions, drinking habits, land drainage, agricultural practices, railways, literacy schemes, communications networks, family planning programmes, meteorological services, health care, airlines and, inevitably, military systems of all shapes and sizes. Nor is there any sign that the pace in systems-exporting will slacken: indeed the newly-rich oil countries are a ready-made market, as every industrialised country knows. But what, besides the staple military diet, is likely to be an attractive system to sell in the 1980s and 1990s? One completely new item is likely to be the earthquake early-warning system.

Few can now be ignorant of the remarkable strides taken in earthquake prediction in the past ten years. Very few quakes have yet been accurately predicted, but the pace of scientific advance and the lessons now being learnt about public response in various parts of the world to the issuance of warnings make it almost inevitable that over the next few years a few countries, notably China, the Soviet Union, Japan and the United States are going to make major strides in learning how to save lives. But many of the most predictable earthquakes probably occur in other parts of the world—Turkey, Iran, the Philippines, Mexico, Central America, Peru, Chile and so on, and many of these countries look very attractive propositions to the politically-oriented travelling salesman.

A national earthquake warning system will require hundreds of widespread installations, the development of a data network and a lot of involvement of the local inhabitants, especially if the more unusual predictions of earthquakes, such as animal behaviour, assume importance. It will be seen to be a worthy altruistic enterprise, proof that the government is concerned. It will also cost a lot of money. It looks absolutely made-to-measure as an exportable system. The question is not so much whether but how.

If the 's' in its name means anything at all, there is surely a strong case for Unesco to take a long look at the problem. For although warning systems would undoubtedly be good things for many countries, these same countries can do without latter-day economic imperialism, often in the guise of overseas aid. An alternative means of delivering effective systems without the imperialist content will not be easy to find, but it is at least worth making a serious effort to do so at this stage. For time is getting short. □

Overdue: another scientific revolution

J. Tuzo Wilson, Director General of the Ontario Science Centre in Toronto, argues the case for a return from growth to stability

CERTAIN major turning points in the history of science can be called scientific revolutions. Their influence is not confined to science, for they have solved philosophical puzzles and changed economies, but their importance warrants a search for new revolutions. It might be fruitful: history shows that earlier scientific revolutions have cast their shadows before them and have progressed through several parallel stages.

Before each of the past revolutions, for example, their old theories worked well and were useful. Their value has been partly hidden by subsequent attempts to denigrate them: before Copernicus, Ptolemaic astronomers had invented the calendar, predicted eclipses and acted as navigators for Columbus and Magellan; biology, classical physics and geology were similarly useful and well-developed sciences, even before the revolutionary discoveries of Darwin, Becquerel and Wegener. The triumph of each of the new theories was due to important new discoveries, observations or ideas which the old theories could not explain, as the observation of the phases of Venus, the discovery of radioactivity and realisation of the significance of mid-ocean ridges and paleomagnetism all demonstrate.

In each case the great event marking the revolution revealed contradictions and introduced problems which the old theory could not resolve, leading to a period of confusion. For the most part it was not experts but rebels, outsiders and interlopers from other fields of science who suggested the need for a revolution and produced the evidence supporting it. Thus most geologists continued to oppose the concept of continental drift long after Wegener (a meteorologist) had championed it, after physicists had provided key evidence supporting it and after many of the public had accepted it.

So, far from welcoming the new ideas, the establishment, who had the most to lose, clung for as long as possible to the old, justifying their position by questioning the new data, discrediting those who advanced them, and trying to patch up the old theories. In these endeavours they frequently found themselves supporting quite illogical positions. Before each revolution was accepted, the state of the subject had become chaotic, but each solved many problems so that the ensuing periods were times of great scientific progress and material benefit.

When one now looks for a field ripe for a scientific revolution the only likely candidate appears to be the marginal science of economic theory. It seems to meet most of the criteria advanced. To the extent that the steady increase in wealth over the past few centuries can be attributed to theory, economic theory can be held to have been successful. But any examination of nature or of primitive societies or any consideration of the mathematical consequences of continuous growth will show that stability is normal and growth abnormal. The history of the West since the Renaissance, and particularly since the start of the Industrial Revolution, has been one of growth. It has made most of us forget that this is unusual and must end.

Now an event has occurred which is so important that it is altering the course which history has maintained for several centuries. The cause of the period of growth and the reason for a delay in fulfilling Malthus' predictions has been that for several centuries energy has become ever more abundant at ever less cost. The oil embargo and the quadrupling of the price of crude oil has ended this period and marks a turning point in history. Some say we must seek substitutes. This is not as important as many seem to think, because many are already available. What is needed is the recognition that no substitutes, either known or awaiting discovery, are at all likely to be so cheap. It seems probable that holes drilled in the ground to produce petroleum have been cheaper than any mines, factories or collecting devices which can be built to generate other forms of power are likely to be.

But matters go further. The old system has broken down. There is a recession from which economies are not emerging as the old cyclical pattern predicted. There is unemployment coupled with inflation. In addition, many organisations and individual members of the general public since Malthus have recognised the coming breakdown, seen that growth can only be temporary, and predicted change. It is not right to say that history has proved Malthus wrong. Fundamentally his ideas were correct, but living in the eighteenth century he did not see that development of power from steam, electricity and internal combustion engines and the whole industrial revolution would delay their impact.

Moreover, the establishment, blind to logic, denigrates those who foresee the inevitability of change as "doomsters", and clings to theories which if they have not broken down completely already are mathematically certain to do so before long. The differences between those who advocate growth and those who predict no-growth is not as great as might be imagined. The supposed economic experts all demand a return as quickly as possible to an annual rate of growth of, say, 5%. Politicians, businessmen and labour leaders all say that this can be attained, and they well may be right for the next year or two, which is as far as they look ahead, to the next election, next meeting of shareholders, or next signing of a union contract.

On the other hand, any accountant can calculate that an increase in demand of 5% annually will in thirty years produce more than a fourfold increase in demand. Thirty years is a period most people can expect to see, and one for which young people make plans, but a fourfold increase in demand is ridiculous in face of present shortages. Thus the position held by the present ruling establishment, as has happened in past revolutions, has become untenable. As an example, I was astonished that an influential man to whom I advanced these views replied that they could not be right because if true they would ruin business!

It will be difficult to convince businessmen, who for several centuries have flourished upon growth, that growth cannot long continue. It will be particularly distressing to them because in the past the declining cost of energy has rewarded innovation with profit, so that greed overcame man's natural lassitude and aversion to change. Each change—from slaves to animal power, from windpower to steam and from steam to internal combustion engines—increased profits.

In future the changes to more expensive forms of power will decrease profits and this is producing a tendency to cling to existing practices. If supplies become exhausted before this is overcome and adequate replacements made, breakdown and anarchy are likely to result. Therefore it is vital to prepare for a return to a stable society and not fritter away resources which are still available to us trying to stimulate growth when the means to support growth are no longer going to be available.

For each past revolution, however, recognition of the new theory has always made progress possible again. Even after it has been recognised that we must accept an overall economy which is less lavish than before, great rebuilding will be needed. As the supplies of oil and gas run out the whole petroleum industry, for example, will have to be replaced by other industries, ultimately by ones that depend upon renewable resources. We have seen many such changes, for example the change over the past 50 years from coal to oil. These changes involve work and employment.

No growth overall need not mean overall stagnation once the correct direction is recognised and followed. Undisturbed Nature is stable, but it is certainly active. I therefore prefer the term renewal economy to no-growth society. The best chance to avoid ultimate breakdown and anarchy and to maintain any of the present forms of society is to take steps at once to change them. It should be noted that the change in philosophy must be farther reaching than a mere change between one or another existing political party or between a planned society and free enterprise. All the present economic philosophies ignore Nature's and mathematics' edict that growth cannot continue indefinitely. If some extreme governments have achieved conditions of no growth in their countries it is because of their ineptitude, not their desire.

The need is imperative to recognise and to start to implement this great revolutionary return from growth to stability. Its effects are likely to be more traumatic than those of any previous scientific revolution, but can best be ameliorated by early recognition and acceptance. Nearly three years have already passed since the revolutionary turning point in the availability of energy occurred. It is ironic that it would appear that it is the conservative blindness of those who should be leaders, whether in politics, business, or labour, that is the greatest impediment to advance. □

Space: a new phase?

Keith Runcorn and **Paul Coleman** describe plans for a major new effort in exploration and urge more European cooperation

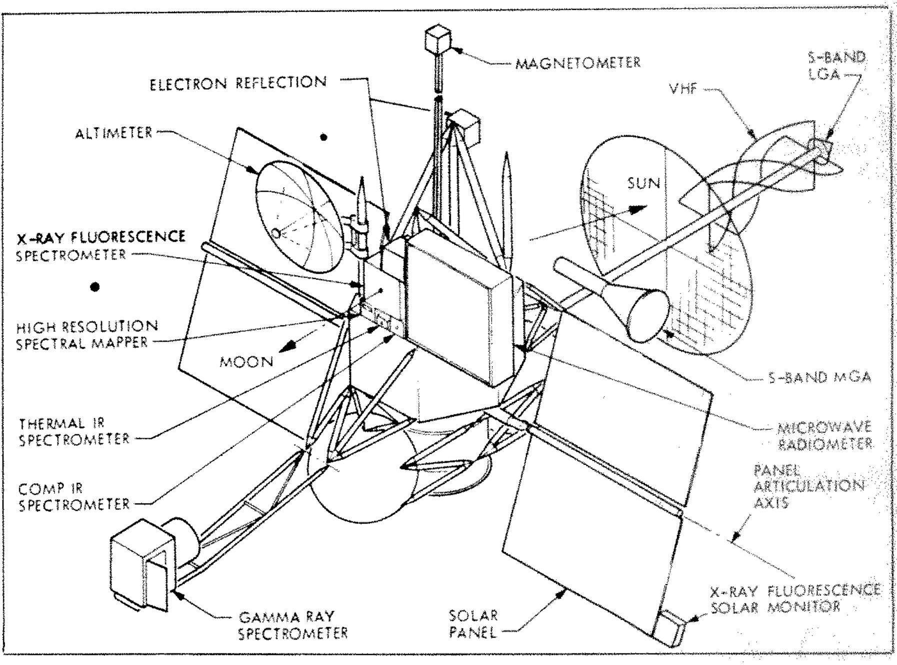
THE landings of Viking spacecraft on Mars on July 20 and September 4, 1976, and of Venera 9 and 10 on the surface of Venus in 1975, mark the culmination of a period of lunar and planetary exploration. Over the past decade manned Apollo landings and the unmanned Ranger, Surveyor, and Luna 16, 20 and 24 landings have been made on selected sites on the Moon. From the data collected on all these remarkable missions, our understanding of the evolution and present state of the Moon and planets is developing at an unprecedented rate. The next decade will see a revolution in our knowledge of the solar system comparable with those studies of continental drift and plate tectonics which, over the past two decades, have transformed our understanding of the Earth.

Europe, with a combined gross national product greater than that of the USA and the Soviet Union, has not so far taken a role which reflects its strength in this field, one of mankind's greatest explorations and scientific endeavours. An opportunity will be afforded by the International Solar System Programme, a project of international collaboration in the exploration of the solar system. The International Council of Scientific Unions recommended last year that all countries should consider how they can most effectively contribute.

Our knowledge of the Moon exceeds in its detail that of any other body in the solar system except the Earth. While it might be feared that sampling the Moon in a restricted number of sites might hopelessly bias our interpretations, it is now clear that the absence of an atmosphere and an ocean and the weaker tectonic forces than on Earth have resulted in much less segregation and concentration of elements and a much smaller variety of rock strata than on the Earth. This has in turn made it possible for the relatively small number of sampling sites to yield data reasonably representative of the Moon as a whole. On terrestrial planets limited samples might not be as successful in determining global properties.

The Moon differentiated about 4.4×10^9 years ago, forming an anorthositic gabbroic crust apparently thicker on the far side than the near side. The sources of the mare basalts, (crystallisation ages 3.2 to 3.8×10^9 years) which filled the great impact basins left in the Moon after catastrophic bombardment, seem to have differentiated at the same time. The processes that brought about this differentiation are obscure and the depth to which it extended is unknown. If the Moon is found to possess an iron core, this early differentiation must have occurred throughout the Moon. The siderophile and volatile elements on the Moon are depleted relative to the Earth and meteorites: information potentially a key to our understanding of the early evolution and origin of the Moon.

Three entirely unexpected charac-



JPL

Flight configuration for TBOL

Keith Runcorn is at the University of Newcastle-upon-Tyne. Paul Coleman is at the University of California, Los Angeles.

teristics were established from physical studies: large positive gravity anomalies over the circular mare (the mascons), moonquakes both deep and shallow, and widespread magnetisation of the crust. The interpretations of these discoveries are still controversial but we conclude that in its early history the Moon was much more active internally than it is today. If so, why has the Moon died?

The interpretation of gravity field on the near side requires an equally complete survey on the far side. Basins of comparable size to the mare are known to exist on the far side, but they are not filled with lava and whether they have negative or positive gravity anomalies is uncertain. Thus, the exact delineation of gravity above these far-side basins is of critical importance to the understanding of the process which resulted in the flooding of mare and the production of mascons on the near side.

Again, the controversy concerning the interpretation of the magnetism of lunar rock centres upon whether the moon generated, between 4×10^9 years and 3.2×10^9 years ago, a general magnetic field which it does not have today. The direction of magnetisation of the lunar crust was impossible to determine by the methods used in terrestrial paleomagnetism; the Apollo samples were unoriented. Instead, interpretation of magnetic anomalies must be used. The existence of an iron core in which a dynamo process might once have been active remains in doubt. A more accurate value of the moment of inertia factor (0.4 for a uniform sphere) which is now given as .392±.003 could resolve this particular matter.

The definitive solutions of many interesting problems raised by existing data depend on completing the survey of the moon which has been so well begun. To this end the lunar polar orbiter has been conceived in a mission named at present the Terrestrial Bodies Orbiter–Lunar (TBOL). A satellite carrying a variety of remote sensors would be put in lunar orbit about 100 kilometres above the surface so that a complete and relatively detailed sur-

The experimental programme

The geochemical experiments consist of a solid state (germanium) counter for gamma rays and four proportional counters (three looking at the moon and one at the sun) for X rays. The former will detect both the radioactive nuclides K, Th, U and the elements Fe, O, Si, Ti, Mg, Al, Ca (in declining order of detectability) excited by the galactic cosmic-ray neutrons and by solar flares. The latter will detect the characteristic X rays emitted from Al, Si, Mg for the quiescent sun and also Ca, K, Fe, Ti during flares. The sampling depth will be 15 cm for the gamma rays and 10 μm for the X rays and spatial resolutions will be 50 km and 10 km, respectively. These experiments will provide much more detailed elemental abundance data than has so far been available and will contribute to the understanding of the differentiation of the moon, especially of the highland regions thought to be anorthositic gabbroic in character but only on the basis of fragmentary samples.

Water of the moon, perhaps retained in the regolith of deep craters near the poles, is exciting much interest and the gamma ray experiment may detect it from the 2.22 MeV line de-excitation of deuterium produced by slow neutrons created in material on the lunar surface by cosmic-ray bombardment.

The radioactivity is known to be greater in the western mare, so that an experiment to detect the surface heat flow is proposed. It may be surprising that this can be done from orbit, but microwave radiometers (3 cm, 10 cm, 20 cm)—three identical beams with 50 km resolution—detect the black body radiation from different depths (down to about 5 m) in the regolith where, because of its extremely low conductivity, the vertical temperature gradient is large. These radiometers and infrared detectors will also measure the lunar daily inflow and outflow of solar radiation, from which the thermal conductivity of the regolith can be calculated. Thus the distribution of heat sources within the moon will be globally mapped and hypotheses such as convection in the interior will be tested.

Reflectance spectroscopy techniques over wavelengths 0.35–2.5 μm will be used to determine the mineralogical composition. This method has already been used effectively to determine the composition of the major satellites of planets. The wavelength of absorption lines from the excitation of electrons from Fe^{++}, Fe^{+++} and ions of other transition metals are influenced by the crystalline structure of the SiO lattice. It will be supplemented by spectro-stereo images with six filters. The latter instrument, of course, will also provide, in high resolution (~100 m), further details of the morphology, stratigraphy and, through crater counts, chronology of the lunar surface.

Magnetic maps of the moon will be obtained at the orbital altitude by a 3-component magnetometer accurate to 0.1 γ and at the surface by an electrostatic analyser of electron fluxes. The latter will detect low energy electrons, spiralling around the lines of the solar wind magnetic field, which are reflected from the convergence of the field lines produced by surface magnetic anomalies. These two methods will complement each other as crustal magnetic anomalies having sharp contrasts of magnetisation look very different at the surface and at heights of 100 km. As various interesting explanations of the magnetisation of lunar rocks have been suggested, some involving cometary and meteoritic impacts, data on the general morphology of magnetic anomalies may establish whether or not these external sources or a magnetic field originating at the lunar core are responsible.

The existence of a lunar core can also be investigated by observing the electromagnetic response of the moon as it enters the fairly steady geomagnetic tail field. The core acts initially as diamagnetic and then the induced dipole moment begins to decay—from this initial decay the free decay time constant of the electric currents in the core can be determined.

The map of the gravity field on the near side will be improved by tracking of the orbiting satellite. For the far side of the moon, complete maps will be made of the gravity field, of which at present nothing is known except by inference from the evolution of the orbital elements of the subsatellites launched in the Apollo 15 and 16 missions. The closely related study of the figure of the moon has been controversial, as the coverage of the laser altimeters on the Apollo 15, 16 and 17 missions has been very limited and the classical earth-bound method, using the geometrical librations which enable height determinations to be made by the parallax principle, were extremely noisy. The radar altimeter in the orbiter should enable the surface to be mapped completely to a high accuracy. The moon departs from a sphere in a variety of ways and the mapping of the moon will be very important to refine our understanding of its non-hydrostatic shape.

vey would be possible. A radio-relay satellite would be put into a more distant orbit to provide an almost continuous radio contact between the instrumented polar orbiter and the Earth. Such a mission, in which the scientific aspects have already been developed (see figure and box), is under consideration by NASA for a 1982 launch (see following story).

The Terrestrial Bodies Orbiter–Lunar mission is part of a new phase of planetary exploration, by means of remote-sensing orbiting spacecraft. A somewhat similar approach, but with a spinning spacecraft, is now under way in the United States for exploration of Venus, and a Jupiter orbiter is in the planning stages. These latter two missions will also involve atmospheric probes, which are unnecessary for planets and bodies without a substantial atmosphere. Modified versions of the TBOL spacecraft could extend further the exploration of such bodies in future.

More active European participation at this crucial stage in the exploration of the solar system would be timely and would enable European scientists, who contributed so much to the analysis of lunar samples, to revive the old scientific tradition of which we have been reminded in recent years by the anniversaries of Copernicus, Kepler and Galileo. □

USA

Ford's parting gifts

Colin Norman in Washington reports on the proposals for research and development in Mr Ford's third and final budget

WITH just three days of his brief and troubled Presidency left to run, Mr Ford this week presented Congress with a complex and detailed set of budget proposals for the 1978 Fiscal Year, which begins on October 1, 1977, more than eight months after he leaves office. Though they are likely to be substantially revised, both by the incoming Carter Administration and by the Democratic-controlled Congress, Mr Ford's parting economic proposals could result in substantial increases in support for science and technology, particularly for basic research.

The proposals represent the lame-duck Administration's detailed prescriptions for limiting growth in Federal spending, reforming the sprawling government bureaucracy and setting priorities among Federal programmes. During the next few weeks, President Carter and his economic advisers will sift through Mr Ford's budget and offer a raft of amendments to bring it into line with the new administration's economic and political philosophies. Carter will concentrate on the more political proposals, however, and it is likely that many of the less controversial programmes, which include most concerned with science and technology, will survive the change of administration more or less intact.

Mr Ford's budget includes a total of about $26,300 million for research and development, an increase of about 8% over estimated expenditures this year. As in the past few years, defence and energy research and development account for the bulk of the increases, but basic research is also singled out for favourable treatment, rising by about 9%, to reach some $3,000 million. Inflation is expected to hover around 6%, so the Ford budget proposals should result in a modest, but real, growth in Federal research support.

According to a discussion paper published by the Office of Management and Budget, funding for basic research in the United States has declined by about 27% over the past decade, chiefly because funding increases have not kept pace with inflation. Although the document suggests that basic science in the United States is competitive with that of other countries, the decline in support "has raised concerns about whether the United States might not be underinvesting in basic research to the detriment of the nation's future".

The chief beneficiary of the proposed increases is the National Science Foundation (NSF), scheduled for an increase in funds for some 12%. According to Richard Atkinson, the acting director of NSF, a major use of the proposed increase will be to upgrade scientific instruments and equipment in universities and colleges. NSF's total budget is set to climb to $885 million under Mr Ford's proposals.

The budget is the first to be produced since the establishment of the White House Office of Science and Technology Policy (OSTP), and some credit for the proposed increases is being claimed for the new arrangement. H. Guyford Stever, the head of OSTP and Mr Ford's science adviser (who will also leave the Federal Government this week) notes with some satisfaction that "although it is a constrained budget, it is not as constrained as in previous years". Asked whether he expects the Carter Administration to go along with the proposals, Stever pointed out that few of the research and development proposals have political implications, and he suggested that "if the incoming administration asks for advice on the research and development budget it would get much the same advice" as Mr Ford received. Since Mr Carter had not chosen a replacement for Dr Stever at the beginning of this week, he does not seem to feel an urgent need for such advice.

Included in the budget proposals are a number of new programmes which have been waiting in the wings for some time, and which are likely to meet with approval from the Carter Administration. Prominent among them is a major effort in earthquake research. A three-year project divided between the National Science Foundation and the Department of the Interior, it is expected to receive about $150 million, with the first instalment of $23 million coming this year. The goals are "development of a reliable prediction capability within 10 years through increased research on fundamental causes of earthquakes and precursor phenomena", establishment of building codes for structures in earthquake prone areas, publication of regional hazard assessment maps, and studies of the social, legal and economic implications of reliable earthquake prediction capability. Such a programme was recommended last year by a White House Advisory Committee, and a similar effort was incorporated in a bill passed last year by the Senate. The Carter Administration is unlikely to reject the proposal.

Another area to receive some long-overdue support in Mr Ford's budget is agricultural research. Some $28 million has been proposed for a new programme of basic research on photosynthesis, nitrogen fixation, crop productivity, and genetic engineering of crop plants, funded through a system of competitive grants similar to those operated by the National Science Foundation and the National Institutes of Health. At present, virtually all the research supported by the Department of Agriculture is funded through block grants to institutions, and initiation of a competing grants programme has long been recommended, particularly by committees of the National Academy of Sciences, as a way to increase the quality of agricultural research. The proposed programme is virtually certain to receive a warm reception in Congress since the House last year approved a bill designed to initiate just such a programme.

Space science is also singled out for a modest increase in Mr Ford's proposed budget. A new start has been proposed on the construction of the Large Space Telescope (LST), a 2.4-metre optical telescope which is expected to be launched by the space shuttle in 1983. Estimated to cost a total of between 435 and 470 million dollars, the LST has consistently been ranked as a top priority space science project by the National Academy of Sciences, but restrictions on federal expenditures in the past two years have twice caused the programme to be deferred. Funds have also been proposed for another high-priority mission, construction of a spacecraft to orbit Jupiter and send probes into the planet's atmosphere. And finally, Mr Ford's budget includes funds to begin construction of three more shuttle orbiters, in addition to the two which have already been approved. There are, however, some casualties in NASA's budget, most prominent of which is a proposal to place a spacecraft in a polar orbit around the moon (see page 197). A start on that mission was anticipated in the 1978 Fiscal Year, but it has been deferred, at least until 1979. So far, Mr Carter has made few public comments about the space programme; thus the fate of Mr Ford's proposals for NASA are uncertain. The projected total costs of the LST may, however, make it a plum target and there is some speculation that Carter will ask NASA to seek foreign financial participation in the project.

One area of Mr Ford's research and development budget which is likely to be substantially modified by the Carter Administration is the proposed funding for energy research and development. Though Mr. Ford has recommended a hefty increase in total support for energy programmes, with some $3,000 million included in the budget for research and development, much of the additional money would be swallowed up by nuclear energy research efforts. The Liquid Metal Fast Breeder Reactor (LMFBR) programme alone is scheduled to increase from 686 to 855 million dollars. During the election campaign, Carter promised to reduce the priority of the LMFBR project and to seek international participation in it. He also consistently promised to try to reduce United States' reliance on nuclear power.

A particular focus of conflict between Ford's energy proposals and Carter's election promises is likely to involve programmes designed to increase energy conservation and to spur commercial introduction of solar heating devices. Mr Ford's budget would involve virtually no increase in funds for research and development on energy conservation, chiefly because the Ford Administration believes such efforts should be the responsibility of private industry rather than the federal government. Similarly, the proposed Ford budget would reduce federal support for a programme designed to provide subsidies for the production and installation of solar heating devices. Again, the argument is that the technology is relatively well developed and private industry should bear the chief responsibility for its commercialisation. Throughout the election campaign, Mr Carter frequently promised to make energy conservation and the development of alternative sources of energy his top priorities. Moreover, James Schlesinger, the former head of the Atomic Energy Commission, whom Carter has named as his chief energy adviser, has also argued strongly for increased efforts to stimulate energy conservation. The thorny question of government involvement in private industry, and Federal subsidies to spur commercial development of those technologies, will clearly have to be addressed very soon by the new president and his energy team. As for fusion energy, Mr Ford's budget provides funds for construction of a large Tokamak device at Princeton University—a project which was reported to be in jeopardy at one stage in the budget deliberations—and it also contains funds to increase the already sizeable fusion project at Lawrence Livermore Laboratory.

Another area which is likely to be a source of controversy is support for biomedical research. The Ford budget provides very little increase in support for biomedical research funded by the National Institutes of Health (NIH), and in particular it seeks to hold the budgets of the National Cancer Institute and the National Heart and Lung Institute approximately constant, after several years of rapid growth. There is also a proposal to transfer responsibility for NIH's intramural research to the Assistant Secretary for Health, a suggestion which is likely to raise considerable protest from biomedical researchers since it smacks of increased political control over health research.

Ford tried to hold down spending by NIH in his two previous budgets but Congress has refused to go along with the reductions and instead it has voted hefty increases for biomedical research. The same pattern is likely to be repeated this year, but the Carter Administration will soon be forced to take a close look at priorities in biomedical research. In that regard, a study produced last year by a presidential commission recommended that there should be some changes in the privileged political position of the National Cancer Institute, but the recommendations have so far been neglected.

Finally, it is worth noting that when President Ford entered the White House in August 1974, he inherited, among other troubles, a scientific community which had been complaining bitterly about declining research support and the lack of a central science policy office. In his brief term of office, Ford has taken several steps to attend to the concerns of the scientific community, and when he leaves the White House this week, he will bequeath his successor a much more healthy scientific legacy. ☐

SWEDEN

Reforming the Councils

Wendy Barnaby reports from Stockholm on proposals to reform Sweden's Research Councils

THE reform of Sweden's Research Councils due to go into effect on July 1 this year is basically an attempt to set up a structure which will accommodate both society's need for research that produces usable and useful results, and the scientists' traditional demand for freedom in conducting research. Of course, any attempt to fuse these two is only as good as the mechanisms whereby fusion is to be brought about—and the will of the people involved to make it stick. But the mechanisms, at least as explained by Mr Jan Stiernstedt, Permanent Secretary of the Ministry of Education and chairman of the reform's organisational committee, look like a model example of the Swedish genius for balance and compromise.

Within the sphere of the Ministry of Education there are at the moment five Research Councils (Humanistic, Social Science, Medical, Atomic and Natural Science), with an average membership of eighteen plus a chairman. In the budget year 1975–76 they were allocated about 6% of the state's expenditure on research and development, which itself made up 3.3% of the total budget, so they are hardly financial giants. In fact, as far as research and development goes, they embody precisely that weighty meagreness which is the essence of prestige—and that they certainly have. Their various structures have resulted from haphazard growth reflecting the enormous post-war increase in the breadth and complexity of research; the reform aims to tidy them up organisationally as well as to make them more sensitive to public interests.

It envisages only three councils (Humanistic and Social Science, Medical and Natural Science), each with ten members who will hold office for six years, and a chairman. The actual number of members will thus have been reduced to a third of its present total, an attempt to make the new bodies more effective. At the same time, however, they are to be made as representative as possible of the views of the academics in each field. Seven members of each council are to be elected from the universities and institutes of higher education, where small assemblies will be elected by those members of staff who have a

USSR

● The recent announcement that the Soviet Union will sell 200 tonnes of heavy water to India for use in the Rajasthan Atomic Power Plant reveals a certain modification in Soviet policy, regarding both aid to India and the non-proliferation of potential nuclear armaments.

Although the first Soviet–Indian mutual cooperation agreement is now more than five years old, India has until now received relatively little technological aid from the Soviet Union, either as hardware or expertise. During the visit of Mrs Indira Gandhi to Moscow in June, 1976, the 'strengthening' of such cooperation was one of the main topics of discussion. The heavy water sale would appear to be one of the fruits of these talks.

Heavy water is, of course, a sensitive topic as far as India is concerned. Although she can produce a small amount of her own, this is not sufficient to supply an installation the size of the Rajasthan power station. Originally, India obtained heavy water from the USA and Canada; the connection with India's explosion of a nuclear device led Canada to cut off supplies, and later to make the ban permanent following unsuccessful negotiations on inspection and safeguards.

The Soviet Union has always shown considerable caution regarding nuclear exports. A recent *Pravda* article, while not referring directly to the Indian deal, emphasises the role of the Soviet Union, within the IAEA, the "London Club" of nuclear suppliers and the United Nations, in "organising monitoring operations". The article stresses the need to increase the efficiency of such international control, and quotes the Soviet non-proliferation memorandum to the 31st UN General Assembly emphasising the "special responsibility" of the nuclear powers and the need for "strict guarantees that international cooperation in the peaceful use of nuclear energy should not become a channel for the proliferation of nuclear armaments".

The Soviet Union has presumably found some way to extract from India the kind of guarantees which, after two years' negotiation, Canada was unable to obtain.

● The filling of the Nurek reservoir on the river Vakhsh in Tadzhikstan has been halted at the 140 m mark on the 300 m dam, on the advice of a joint Soviet–US geophysical team now working in Tadzhikstan under the terms of the Nixon–Brezhnev cooperation agreement.

Commenting on the decision, the Academic Secretary of the Soviet Academy of Sciences, I. Ivanov, noted that the dam is situated in the only region of the continental part of the globe where as many as 2,000 tremors occur annually. Filling of the dam has produced a marked increase in seismicity and, according, further raising of the water-level will take place very gradually. There is no suggestion, however, that the planned final capacity of the reservoir will be reduced.

● One of the anomalies of Dr Veniamin Levich's position as a *refusnik* is that although he is no longer permitted to work as a scientist he still retains his position as a Corresponding Member of the Academy of Sciences. The Academy itself still retains a certain autonomy, and according to its statutes requires a two-thirds majority vote in secret ballot for the expulsion of a member. When an Academy meeting to discuss draft changes in its rules was called for December 22, 1976, Academician Levich wrote to say that he wished to speak at the meeting, to propose a statement clarifying the moral responsibility of Academy members. He was informed in due course that the said meeting had been postponed until February 1977, "when this proposal will be entered".

In proposing the statement, Levich clearly wished to draw attention to the plight of dissident scientists. It should be noted, however, that the last time a number of Soviet Academicians made a declaration on 'moral responsibility'—as individuals, and not as a corporate body—was during the 1973 press campaign against Andrei Sakharov. They declared then that the first duty of a Soviet scientist was uncompromising support for the State.

Vera Rich

PhD. These local bodies will together form a national assembly, which will then elect the council members. The other three members will be appointed by the government and will represent the various official bodies that exist here within each field: the Environment Protection Board and the Board of Education, for example, within the humanities and social sciences. The chairman will be appointed by the government. Each council is thus to embody the principle of scientific freedom by having members drawn only from within the field. The fact that a majority of members will be elected by active researchers will bend the councils in the direction of current interests.

But what happens if enthusiasm for current research interests solidifies into unwillingness to risk failure with newer or simply unfashionable ideas? This is a criticism made by one prominent Swedish medical scientist of the existing Medical Research Council. It is precisely to prevent the conventional wisdom of the dominating group within any field from restricting other impulses that the reform was undertaken. And as the impulses to be encouraged are those which come from the broader society, the main innovation of the reform is the creation of a special body to give them a persuasive voice—the Research Councils Coordinating Board.

This will exist alongside the councils and have two main tasks: to coordinate administrative procedures amongst them and to promote cross-disciplinary research projects of interest to society in general and needing cooperation between the different councils, institutes and boards. It will consist of a chairman, to be appointed by the government, and twelve other members, one to be appointed from each of the three councils, the Agricultural and Forestry Research Council and the Board for Technical Development, and the other seven to be appointed by the government as elected representatives of the community. At least four of them are to be members of parliament, and the others will come from local government and trade unions. In order to back up its suggestions, the Board will dispose of funds estimated to total at least Sk30 million (nearly US$57 million) by the budget year 1979–80.

Attempts to involve parliamentarians in Swedish science policy have so far been remarkably dull. But they have never been underwritten with funds, and money, as Mr Stiernstedt points out, is to be the key to the new Board's influence. If the Board can offer to fund a project, organisational inertia will in many cases be overcome. The Board will be able to stimulate but not dictate; every council will retain the right to decide which projects it will participate in. Finally, then, the scientists—if they want to—will be able to discount the Board's suggestions. On the other hand, they could make use of its resources to widen not only society's outlook, but also their own. ☐

NETHERLANDS

Satellite plans

Casper Schuuring reports from Holland on the latest Dutch commitment to space research and astronomy

AT the end of 1976 the Dutch government finally decided to finance a second astronomical satellite, to be launched by NASA with a Thor Delta rocket in the spring of 1981 from the Western Test Range in California. After the success of ANS, the first Astronomical Netherlands Satellite, in the field of soft and hard X-ray and ultraviolet radiation, the second satellite (IRAS) will do observations in the infrared.

The project started in January 1975 with a preliminary definition study. When contacts were sought for the scientific programme with NASA and the European Space Agency (ESA), there was an enthusiastic response, especially from the US community, at the prospect of stimulating this branch of astronomy. Following a NASA "announcement of opportunity" 13 proposals for experiments came in. A US study team consisting of 11 astronomers started discussions on the IRAS mission with their Dutch colleagues.

At the beginning of 1976 agreement was reached on the scientific programme and NASA expected a memorandum of understanding between the US and the Netherlands to be signed before July, 1976. The Dutch government agreed in principle to the project in July, in spite of a curtailment of expenditure generally, and it took six months to find the necessary money.

The United States and the Netherlands will both have to pay around 110 million guilders (£1 = DG 4.15). Out of the discussions with the ESA, moreover, a British interest arose, and the UK Science Research Council took an active part in the US–Dutch negotiations. Britain is contributing 10 million guilders, for the most part consisting of facilities for flight operations in the Appleton Laboratories in Slough.

The design and building of the satellite represents a challenge to Dutch industry, and especially Philips and Fokker-VFW, which hope to continue the industrial innovation which resulted from the ANS project. A British advisory group, General Technology Systems Ltd, provided evaluation of the possible profits of space activities for the Netherlands in the coming years and of the IRAS project in particular. The results of this study are said to be favourable and support the new project.

The great amount of data from IRAS will make higher demands on storage and retrieval than with ANS. Large scale integration techniques will be used in the on-board computer, giving it a maximum of calculating capacity (500 million bits per day). Also of an advanced design is the extreme cooling system for the telescope and the detectors. Infrared observations are only possible if the instruments are cooled close to absolute zero. A special helium-cooled vessel has therefore been developed.

The results of the IRAS mission, the plan of which was set up in June, 1975 by a commission of 15 American, British and Dutch astronomers, will be received in time to be used for the detailed programming of the experiments with Spacelab in the 1980s. Over a six-month period a survey will be made of infrared sources in the Milky Way and infrared radiation from extra galactic systems. In the following six months more detailed measurements on different sources will be carried out. The astronomers hope to trace and map some 10 million infrared sources. The 925 kg satellite will fly in a circular polar trajectory: one earth orbit will take 124 minutes, so that a sun-synchronous trajectory on a height of 900 km is followed.

Not everybody is as enthusiastic as the astronomers, however. Dutch associations of scientific workers protested in 1974 against further Dutch space activities. At that time an agricultural satellite for underdeveloped countries was under study, as well as the IRAS. This project was not then as far advanced as IRAS, and the benefits for these countries from it were considered small because they lacked the necessary infrastructure. The associations were also against IRAS, as "this type of research would hardly contribute to solve the real problems in the world". ☐

IN BRIEF

Computing costs

For the second time in three weeks the UK Computer Board for Research Councils and Universities has drawn attention to the problem it is facing with rising costs. In its Sixth Annual Report published just before Christmas (Cmnd. 6696, HMSO, 45p), the Board expressed concern at the rapid increase in recurrent expenditure at university computing centres. These had resulted mainly from staff salary rises and increased maintenance costs. The Board added that it was "unlikely" that all recurrent commitments could be met, and that criteria were being sought for the equitable allocation of the funds available. This is expected to be a tortuous process.

Last week the Board published a report outlining the policy framework the Board considers necessary for the development of university computing facilities over the next ten years (*Computers in Higher Education and Research: The Next Decade*, HMSO, 60p). Concern about costs was again emphasised but the cause became clearer when a figure was put on the rise. From the 1975–76 level of £6.2 million, the trend is for recurrent costs to rise—"at a rate of 32%". And the figure is an annual one, though the report does not make this clear.

The Board estimates that university computing facilities proposed for the next decade could be obtained at a capital cost of £9.4 million a year. It adds that "it is not entirely clear" that the government's procurement policy favouring ICL has been beneficial "either to the universities or to ICL".

Uranium views

If opposition in Australia to the development of nuclear fuel resources is successful, scientists who want to become part of the development of uranium mining and processing and of nuclear power will have to leave the country, according to Sir Charles Court, the premier of Western Australia. Responding last week to scientists who have urged the national government to ban uranium mining and exports, he described their attitude as "negative and defeatist".

Aspects of the mining and processing of uranium were the subject of a symposium held in London this week. One presentation, from Michael Davis of the European Commission of the EEC, argued that European uranium needs in relation to the world market were of paramount importance to the market's future. "Close collaboration" between utilities and mining companies was highly desirable, and a contribution from the public authorities was necessary to achieve an orderly market.

Peer review

THOMAS H. JUKES

It has been said that the warp that holds the complex fabric of science together is peer review, and the woof is the noise made by scientists who complain about it. Be that as it may, it is obvious that without peer review, scientific literature would become a Tower of Babel. One has only to look across the street to see what goes on in the newspapers for reassurance as to this point. Science is essentially hierarchical; its progress and its integrity depend on the existence of an 'establishment', and on the rejection of uncontrolled or unrepeatable experimental results. There are objectors who say that such rigidity prevents valuable innovations from coming to light. The answer to this may be formulated as a Darwinian analogy: such innovations are like the exceedingly rare class of mutations that are beneficial to a species, and hence overcome all odds against their survival and spread.

I am indebted to a lecture by Professor Emilio Segre for an anecdote of Rutherford's rejection, on behalf of *Philosophical Magazine*, of a manuscript by the youthful Bohr, describing a new theory of atomic structure. But the young genius was not to be denied. He journeyed from Denmark to England to confront Rutherford, the giant of physics, and won his point: the famous article was published. The answer to the line in Gray's *Elegy*, mourning the possible loss of "some mute inglorious Milton", may be that Miltons are never mute. Nevertheless, I do not recommend making a trip to the offices of *Nature* to argue with the Editor except under most extreme circumstances.

The word "peer" implies acceptance by a group of equals. The process of acceptance in the group, and acknowledgement of its hegemony by the individual who has been accepted, is complex and fascinating. There are special cases; for example, one of the principles of scientific organisation is that a veterinarian should report only to another veterinarian. I presume that at the head of such a pyramid must be one, perhaps a Dr Cabot, D.V.M., who reports only to the Great Veterinarian. Nobel Laureates are another special case; some of them acquire omniscience after their return from Stockholm, and henceforth they blossom in new fields. This subject is admittedly a delicate one, but I am intrigued by an advertisement in a financial newspaper, appealing for tax-deductible contributions. "Each contributor will be sent an article on sugar—its effect on the body; an article on Vitamin C—how much to take and how it may benefit your life; and a just-published article showing the dramatic effects of Vitamin C on cancer." Idly, I wondered who reviewed these articles that are so temptingly offered in exchange for cash.

Publishing a book is a way of avoiding peer review. Confronted with criticism, the authors of such books are apt to remind their detractors that Galileo was persecuted by the Inquisition, and that sceptics told the Wright brothers that their aeroplane wouldn't fly. In one recent case, the author said that high-quality DNA and RNA can be supplied from outside the body to "nourish our cells and return them to a healthy state." Apparently he had not heard about nucleases, purine catabolism or gout. The publishers of the book, more interested in sales than veracity, allegedly have set aside $20,000 to promote it further. Peer review is evidently of secondary interest when such financial manoeuvres are involved.

And so, to those who chafe under the pettifogging and nitpicking annoyances of the comments of reviewers who "don't seem to understand how important this piece of research is", let us counsel patience, forbearance and cunning. Hang in there, and remember that, after all, if you can't convince the reviewer, you *may* not be able to persuade other readers. Also, you, too, may perhaps be a reviewer some day.

correspondence

Earthquake risk

SIR,—The succession of devastating earthquakes in recent months has vividly borne out O'Keefe *et al*'s conclusion[1] that "natural" disasters are on the increase. More remains to be learned about precursory phenomena before earthquakes can be forecast reliably enough to save lives regularly. Yet much can be done in other ways to mitigate the hazards. Earthquake risk is highest where the probability of earthquake occurrence and the vulnerability of an area combine to maximum effect, and in practical terms it is this that requires quantitative evaluation. Molchan *et al.*[2] have developed a mathematical analysis of earthquake risk but whereas evaluation of earthquake occurrence has attracted considerable attention, through compilation of seismic zoning maps and so on, the evaluation of vulnerability has received much less. Vulnerability is the distribution of loss potential, measured in financial terms, and is given by the actuarial assessment of the damage potential in an area both of material losses and social losses (loss of life, injury, loss of work, family, social disruption).

Planning must attempt to reduce vulnerability in areas of high seismicity, but it would be impracticable to design for total invulnerability. Hence, a measure of degree of vulnerability is needed. Engineers use the concept of earthquake resistance in structural design. I propose a similar concept of earthquake resilience should be used in the same way to assess the social and economic response. Just as engineers accept that some degree of damage to structures in an earthquake must be tolerated, so it must be accepted that some social losses have to be faced. Certain essential services such as hospitals, and fire fighting units may need special protection, both in terms of buildings and personnel. But other structures and services may perhaps be disrupted without long term detriment to the society. The concept of resilience provides a means of estimating the power of recovery of society in the event of an earthquake. With this methodology, the balance can be worked out for an acceptable expenditure to provide a tolerable degree of protection against an earthquake, which can be afforded within the economy of the country as a whole and which forms an integral part of its national development plan.

Significant journals of science

SIR,—The review article of Garfield (December 16, 1976, pages 609–615) contains relevant information in Table 3, where the impact factor (that is, the ratio between the citations in the 1974 Science Citation Index and articles published) of scientific journals is being presented in three specialities. Tables 1 and 2, on the other hand, are misleading. The ranking is by total number of citations. This criterion is invalid for a cross-section of all scientific journals.

In a field, say general medicine, where as a matter of example 10,000 workers each publish a paper with on average 10 references, this means 100,000 citations; material science, with 100 investigators and the same ratio, would yield only 1,000 citations. Thus the total number of citations, and in some lesser measure the "impact" too, are influenced by the total number of people interested in a given speciality.

Of the many factors influencing the number of laboratories working in any given field (besides fashion, inertia and others), last but not least, public funding must also be mentioned. The number of citations is rather a measure of the financial endowment of the field and not of the "significance" of the journal.

The 206 journals cover well established and thoroughly ploughed fields. Somewhat speciously it could be argued that for correlative, innovative, out-of-the-common and modern topics, which have not had time to accumulate citations and large teams, one must look outside of the 206.

Rapid publication

SIR,—Rapid publication has become a topic of increasing importance as the camera-ready method and related methods have become more and more popular, especially for papers presented at symposia and the like. The manuscripts must be prepared by the authors according to special instructions. In small institutions the authors have to do all the processing themselves in addition to preparing the normal manuscript. They soon find out that a paper of 5–6 pages will take three to four weeks of drawing, photographing, editing, and typing according to the instructions. At a symposium with 200 to 250 papers, I would guess at least 100 will be prepared by the authors. This means that over 7 years are spent by scientists in preparing the camera-ready manuscript!

Institutions in developing countries usually tend to be small and have small budgets, and scientists working there are already overloaded with a wide variety of problems inherent in such situations. The preparation of camera-ready manuscripts therefore lessens the costly time which could be spent on actual research. Compared to scientists in well-equipped institutions, the scientists in small institutions see their research activities fall increasingly into arrears. I think that for us and other scientists in similar situations the advantages do not always equal the time and misery of preparing a camera-ready manuscript. I realise that the advantages for editors as well as for well-equipped scientists are quite substantial.

In case camera-ready manuscripts are required, I would suggest that possibilities for technical assistance are created in this respect for those who do not have it, and for which biologists are certainly not trained.

Curacao, Netherlands Antilles

He's repented

The most recent issue of *Scientia Sinica* contains the following correction slip: In the aricle "Devote Every Effort to Running Successfully Socialist Research Institutes of Science" (*Sci. Sin.*, XIX, No. 5), "the arch unrepentant capitalist-roader in the Party Teng Hsiao-ping" should read "Teng Hsiao-ping".

news and views

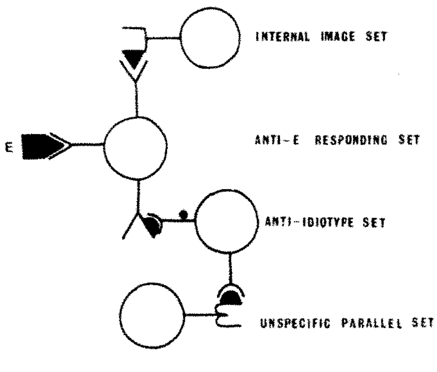
Immunological networks

from Martin Raff

SEVERAL years ago, Jerne proposed a network theory of the immune system[1,2] and predicted that, if correct, its impact on immunology could be as great as that of the selective theories of antibody formation[2]. Although crucial information is still lacking, increasing evidence suggests that he may be right.

Idiotype networks

Antibodies not only recognise antigens, they themselves can act as antigens. Those antigenic determinants (or epitopes) that are related to the antigen-combining site of an antibody are called 'idiotypes'. Jerne suggests that idiotypes are more than just useful tools for immunologists—they may form the basis of a complex immunological network which is central to the functioning of the immune system. He argues as follows. Since the repertoire of antigen-binding sites (and thus idiotypes) in an animal is very large (perhaps $\sim 10^6$), no one idiotypic determinant, in the absence of antigenic stimulation, is present in high enough concentration to induce tolerance. Thus in the course of an immune reaction the increased concentration of specific idiotypes would stimulate anti-idiotype immune responses. Such anti-idiotype (and presumably, in turn, anti-anti-idiotype) responses would play an important part in regulating an immune response. It is known that animals can be stimulated to make antibodies to the idiotypic determinants of antibody molecules produced by other animals of the same species or strain, or even of their own antibodies (see below); and this suggests that an animal possesses antigen-binding sites that can recognise any idiotype occurring in the species. This in turn suggests that within an immune system, any idiotype can be recognised by a set of antigen-binding sites and any antigen-binding site will recognise a set of idiotypes.



JERNE'S IDIOTYPE NETWORK

Thus, a lymphocyte clone, with Ig receptors having an antigen-binding site for epitope E and bearing a characteristic set of idiotype I, can in principle form a functional network with two other sets of lymphocytes (see diagram)—idiotype-reactive cells with receptors having binding sites for I, and cells with Ig receptors bearing idiotypes which are cross reactive with E and thus recognised by the anti-E lymphocyte clone. Jerne calls the latter set the "internal image" set of lymphocytes. A fourth set of cells in this interacting network might consist of cells with Ig receptors bearing I idiotypic determinants but having antigen-binding sites for epitopes other than E. In addition, each of these three lymphocyte sets, which are functionally linked by idiotype to the original anti-E lymphocyte clone, forms its own interacting network with other lymphocytes, also built around the idiotypes of their Ig receptors. Assuming that both T and B lymphocytes share at least some idiotypes[3–5], both classes of lymphocyte would participate in such a functional network, which is in a dynamic steady state with the elements interacting both positively and negatively. Jerne tentatively proposes that the anti-idiotype (anti-I) set of lymphocytes may have an inhibitory effect while the "internal image" set may have a stimulatory effect on the anti-E clone, the overall effect being a "balanced suppression" which must be overcome in order to induce an immune response to E (ref. 2). However, it may be that within each set both stimulatory and suppressive lymphocyte subpopulations are represented.

The immune system is thus visualised as a complex network of antigen-binding sites that recognise sets of idiotypes, and of idiotypes that are recognised by sets of antigen-binding sites. Its response to antigen is, therefore, best understood in terms of a reverberating perturbation of the network, rather than as a response of individual antigen-sensitive lymphocytes.

Many of the elements required for such an idiotype-based network have now been shown to exist. T (refs 6–8) and B (refs 8–17) lymphocytes reactive to idiotypes present on the animal's own Ig molecules have been unequivocally demonstrated. Anti-idiotypic antibodies, administered exogenously[3–5,7,18–20] or produced endogenously[16,17,21] have been shown to suppress[3–5,7,18–19,21] or stimulate[4,20] T and/or B lymphocytes which share the relevant idiotypes, and anti-idiotype-reactive T cells have been shown to suppress the production of antibodies carrying the idiotype[7]. Moreover, it has been demonstrated that the antibody response to phosphorylcholine in BALB/c mice, which is largely restricted to the response of a single clone carrying the TEPC 15 idiotype[22], is accompanied by the production of anti-idiotype (anti-TEPC 15) antibodies[13,15]. Therefore, idiotype-bearing and complementary anti-idiotype reactive lymphocytes coexist in the immune system and, in at least one case of a clonally restricted antibody response[13–15], both sets of lymphocytes are activated during an immune response to an appropriate antigen. What remains to be demonstrated is that such autogenous anti-idiotype reactions occur in the more common situation where the initial response is

Volcano spacing in East Africa

from Peter J. Smith

THE near-rectilinear pattern of volcanoes in the Galapagos Islands was first noticed by Darwin (in *Geological Observations on Volcanic Islands*, London, 1891) and the near-uniform spacing of Hawaiian volcanoes was first observed by Green (in *Vestiges of the Molten Globe*, Honolulu, 1887). Since then, numerous workers have claimed to detect regularities in volcano siting, and some have pointed out that the spacings of oceanic volcanoes in particular appear to be roughly equal to the thickness of the local crust. More systematic attempts to relate volcano spacing to crustal thickness were doomed to failure, however, because (as we now know) the crust is not the correct unit to consider in this context.

Interest in the problem of volcanic intervals therefore largely died out until in 1974 Vogt (*Earth planet. Sci. Lett.* **21**, 235; 1974) revived it in the light of modern ideas on Earth structure. Vogt found that within oceanic provinces volcano spacings are indeed remarkably uniform. In 'continental' subduction zones volcanoes are typically 70 km apart whereas in island arcs they are 55 km apart. The separations of volcanoes associated with 'hot spots', on the other hand, increase with the age of the surrounding oceanic crust. But what, figuratively speaking, links all these volcanoes is the thickness not of the crust but of the lithosphere. Thus Vogt was able to show that within any given volcanic province the distance between adjacent volcanoes is roughly equal to the thickness of the local lithosphere.

But is this also true for continental volcanism? To find out, Mohr and Wood (*Earth planet. Sci. Lett.* **33**, 126; 1976) have examined volcanoes along the northern section of the East African rift (roughly 15° N–5° S). This is a particularly suitable area because, although data are fewer, lithospheric thicknesses are generally better determined than in oceanic zones and are known to cover a much wider range. In any event, there are sufficient data to allow Mohr and Wood to show convincingly that the volcano spacing = lithospheric thickness relationship holds good for East Africa as well and is independent of the type of volcanic rock involved.

Why the relationship holds, apparently universally, is less clear, however. Vogt made two suggestions: first, that a volcano taps all magma within a given radius (a 'scavenging radius') related to lithospheric thickness through a conical volcanic conduit of fixed angle (25°) and, second, that volcanic sites are controlled by lithospheric fracture grids with spacings related to lithospheric thickness. He favoured the latter mechanism, though leaving open the question of whether the grids predate, or are contemporaneous with, the magmatic activity. By contrast, in a situation in which the crust is exposed Mohr and Wood find no evidence at all of volcanic control by pre-existing fracture grids, although again the possibility of contemporaneous rifting remains open.

---

clonally heterogeneous, and that they have an important immunoregulatory role. *A priori* it seems highly likely that they do.

Moreover, it makes sense that just as environmental antigens stimulate and recruit relevant T and B cell clones into the recirculating, long-lived lymphocyte pool, the antibodies and receptor-bearing cells produced in the course of these responses should stimulate and recruit anti-idiotype-reactive clones into the pool; thus, the immune system would organise itself into an idiotype-based network. It should not be difficult to establish that such a network is important in immunoregulation: if eliminating anti-idiotype-reactive T and B cells from a cell population markedly alters the response of the idiotype-bearing clones to the appropriate antigen, the point would be made. From a practical standpoint, the TEPC 15 idiotype response to phosphorylcholine[8,13,15,18] would be an attractive system for such an experiment, but ultimately it will be important to demonstrate an effect in a non-restricted, clonally heterogeneous response.

As Jerne has pointed out[2], the major weakness in an immune network theory at the moment is the incompleteness of our knowledge of the component parts (immunologists are still subdividing T and B cells into an increasing number of subclasses, and the end is not yet in sight) and our ignorance of the mechanisms involved in positive and negative interactions between the parts. The task is clear, and it seems unlikely that mathematical model-building[22,23] will be of great value until more information about the elements in the network is available. In the meantime, the lack of detail makes it possible to use the network theory to explain various immunological paradoxes that are difficult to explain in other ways[2]. For example, it provides, in principle, a way out of the Oudin-Cazenave enigma[24], which is the observation that antibodies produced against two non-cross-reacting epitopes of one antigen molecule may have similar idiotypic determinants. It can also explain another of Oudin's paradoxical observations[25]—that immunisation results in the production of nonspecific Ig molecules bearing the same idiotypes as the specific antibodies; in fact, this suggests the existence of the "unspecific parallel set" of lymphocytes in Jerne's network (see Fig.).

An allotype network

The dramatic observations of the Herzenbergs and their colleagues[26] on chronic allotype suppression have uncovered another type of lymphocyte network, based on allotype rather than idiotype. Allotypes are alloantigenic epitopes on Ig molecules which are unrelated to the antigen binding site and have no known functional significance. In [SJL(Ig-1b)×BALB/c (Ig-1a)]F_1 mice, perinatal exposure to antibodies directed against Ig-1b allotype determinants (present on IgG molecules) results in the generation of suppressor T cells which specifically inhibit the production of all antibodies bearing the Ig-1b allotype but not antibodies bearing the other parental allotype (Ig-1a). Herzenberg *et al.*[26] have now shown that the suppressor T cells in these allotype-suppressed mice do not directly act on Ig-1b B cells, as originally assumed; rather, they suppress a specific class of helper T cells which normally help Ig-1b B cells to differentiate into Ig-1b antibody-secreting cells. Besides indicating that T cell suppression of B cell responses may act indirectly by way of T helper cells, as is probably also the case in carrier-specific T cell suppression[27], these striking experiments demonstrate that, in these mice at least, there are allotype-specific T helper cells, which help only B cells bearing the Ig-1b allotype, and suppressor T cells which specifically suppress these allotype-specific T helper cells. These three sets of cells constitute a lymphocyte network organised around allotype, which, unlike an idiotype-based network, is independent of antigen specificity and would therefore include many lymphocyte sets functionally linked in an idiotype network.

There are however difficulties in inducing chronic allotype suppression using other mouse strain combinations[28], and it is not clear whether allotype networks are the exception or the rule. Nor is it obvious what purpose they serve. Since it is not known whether allotypes have any functional significance one cannot assess the value of regulating immune responses on the basis of allotype. On the other hand, there would be obvious advantages in regulating immune responses on the basis of Ig class. At the moment, the only hint of lymphocyte networks based on Ig class is the report of T helper cells that are specific for IgE B cells[29]. It is possible that the finding of an allotype-based network will point the way to an eventual demonstration of similar lymphocyte networks based on Ig class. In view of the increasing evidence for Ia-bearing molecules with immunoregulatory function, and Ia-bearing cell-surface acceptors for these molecules (see ref. 30), it is also conceivable that there may be lymphocyte networks organised around determinants of the major histocompatibility complex (MHC), just as there are around Ig epitopes.

There are other intriguing questions raised by the demonstration of an allotype-based network[26]. How do the cells in the network recognise each other? The conservative answer would be by the use of allotype-bearing and allotype-recognising antibody molecules. But it has been difficult to demonstrate Ig allotypes on T cells; and the relatively high concentrations of allotype in the serum might be expected to block allotype-reactive receptors on cells. What is the relationship between carrier-reactive and allotype-reactive T helper cells? Apparently, both can be required to activate a B cell, but are they the same cell, with one receptor for allotype and one for carrier? Since evidence is growing that most T cells preferentially respond to antigen in association with MHC determinants (see ref. 30), is it possible that helper T cells have separate receptors for carrier, allotype (and/or Ig class) and MHC antigens? ☐

Ultrasonic assessment of arterial pathways

from C. D. Field

NON-invasive determination of blood vessel function by measurement of Doppler shifted ultrasound reflected from moving red cells is rapidly gaining clinical acceptance as a useful tool in screening for vascular disease. Abnormal patterns in the reflected Doppler-shifted signals compared with those obtained from normal healthy individuals are beginning to be characterised and correlated with various clinical conditions, as defined by conventional radiography and other techniques, and to be used diagnostically. For routine screening, ultrasound has several important advantages over conventional radiography. Injections of toxic dyes are not needed to locate the vessel under study, and because power levels are so low (about $30\ \mathrm{mW\ cm^{-2}}$) measurements can be repeated as often as required.

To detect red cell velocities by Doppler shifted ultrasound two identical piezoelectric crystals are mounted coplanar at an angle to the vessel under study, as transmitter and receiver. Activation of the transmitting crystal produces a narrow beam of ultrasound which is coupled into the tissue by way of a water-based gel. Activation frequencies vary from 1 to 10 MHz and their physical properties are well documented (Gosling and King, *Cardiovascular Applications of Ultrasound*, North Holland, 1973). Incident radiation returns to the receiver from the tissue both by reflection from large surfaces and reradiation by any small elastic particles in the beam path. Donald (*Brit. J. Radiol.* **49**, 306; 1976) has recently discussed the use of reflected radiation from structures of differing acoustic impedance and Gosling (*IEE Medical Electronics Monographs* **21**, 73; 1976) has considered the use that can be made of the backscattered Doppler shift signals from moving blood in arteries.

When a blood vessel is bathed in an ultrasonic beam a wide spectrum of Doppler-shifted frequencies is backscattered from vessel to receiver at each instant of time, because velocities of the red cells vary across the lumen. This spectrum varies over the cardiac cycle and, with beam frequencies of 1 to 10 MHz, is in the audio range for both healthy and diseased arteries. All signals received from a vessel can be displayed as a sonagram—the Doppler shifted frequencies along the Y axis, time along X and blackness of trace proportional to signal amplitude. The striking aspect of sonagrams from any vessel is their well-defined maximum frequency envelope over the cardiac cycle which can be used to characterise an arterial site under specified conditions.

Although certain direct physiological information can be obtained from a single sonagram a great deal more information can be gained by using two simultaneous observation sites at consecutively paired positions along the vascular tree. Phasic changes in such paired sonagrams are easily recognised as 'normal' or abnormal. These changes may be due to trauma, congenital defect or pathological change and the observed differences from normal may be correlated empirically with clinical condition and used diagnostically.

As well as arterial status, functional ability of the heart can be assessed. This is done with one Doppler detector over a neck artery, a second on the chest plus an ECG and a heart microphone. A simultaneous four line trace shows all the cardiac intervals (Gosling, Beard and Pickup, in preparation).

No Doppler shift ultrasound volume flowmeter is yet available for clinical use. However, it has been realised that the shape of the flow-velocity pulse at any arterial site, and hence the flow-velocity sonagram, carries information about the whole cardiovascular tree. Baskett *et al.* (*Cardiovascular Res.* 1977 in the press) has used this approach to estimate the extent of disease in the internal carotid artery supplying the brain (a common source of strokes). An intrinsic property of an artery wall is its compliance. This is defined as fractional change of lumen diameter per 10 mmHg pressure and so may be compared in subjects with differing pulse pressures. Gosling (*op. cit.*) considers that it may be a useful indication of vascular disease and that *in vivo* measurement of this parameter could lead to earlier detection of abnormalities. There is some difficulty in measuring compliance directly but it has been demonstrated that in certain conditions the average value of compliance for any length of artery is given by a simple function of the delay time between entry and exit pulse waves, that is, sonagrams, for the same heart beat and their distance apart on the vessel. This indirect measure of compliance is easily made through the skin, and amounts to determination of the apparent propagation speed of the flow velocity pulse.

The Non-Invasive Angiology Group at Guy's Hospital Medical School, London, has recently applied this pulse wave velocity approach in a study of compliance in aorta, pelvic arteries and leg arteries. They find that aortic compliance in normal subjects increases by some 70% in the first decade for both males and females, decreases to birth value over the next decade and then only slowly decreases over the rest of the life span to about half-birth values in old age. Their results also show that the female diverges from the male at menarche. Women retain a significantly higher aortic compliance until menopause, after which there is again no difference. In patients with diabetes it was found that insulin-dependent juveniles (diagnosed less than one year before measurement) had abnormally high aortic compliance, but that older patients (over 40 years) whose diabetes was controllable by diet exhibited normal or lower values. These results are markedly different from the accepted view that diabetic children and adults always have stiffer arteries than normal. That physiological function may affect structure has recently been demonstrated by Berry *et al.* (*Brit. Heart. J.* **38**, 510; 1976) who showed that compliance of the aortic-iliac pathway is anomalously high in those children born with a single umbilical artery. Such compliance studies as these clearly have implications in the search for causal factors of arterial occlusive disease, the biggest single cause of death in society today.

It may be concluded that Doppler-shifted signals from various arterial sites and pathways of the body can yield much useful physiological and pathological information. Research teams such as those at Guy's Hospital are now able to scan, non-invasively, specific arterial segments (or pathways) and objectively decide whether they are normal or not. Furthermore, this is being done on an out-patient basis in the relaxed unsedated patient. Although still in their infancy as clinical tools, these techniques and methodology offer a complementary approach to conventional methods with obvious advantages to clinicians and patients alike. □

Diamond platelets are interstitial carbon

from John Walker

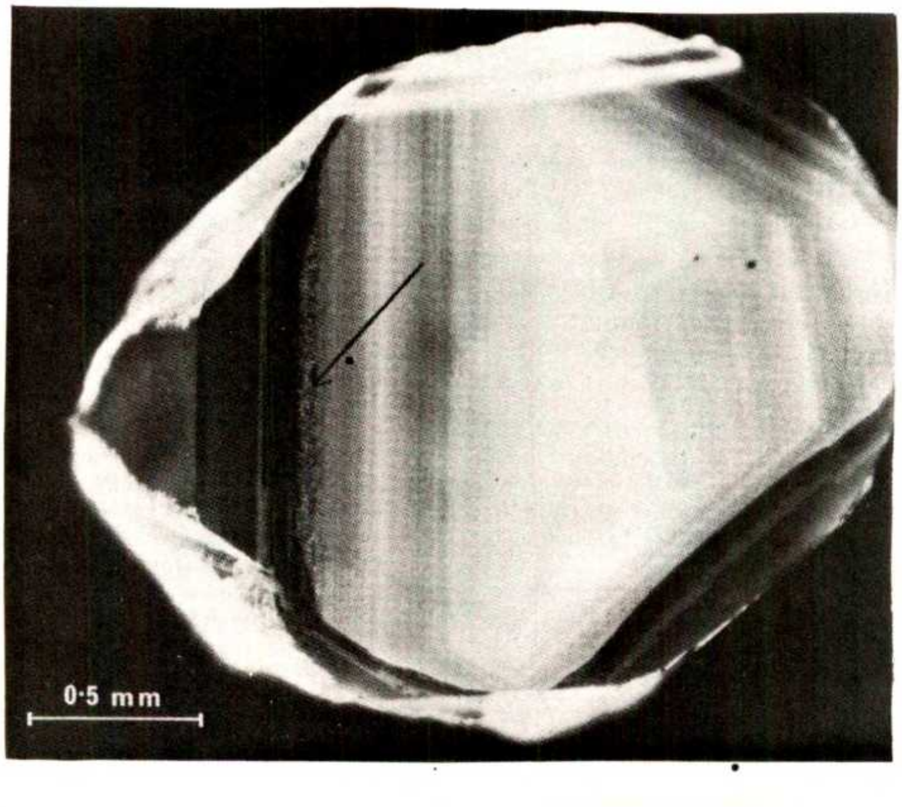
IN a recent *News and Views* item (*Nature*, **264**, 317; 1976) I noted in passing that we were still ignorant of the nature of one of the defects found in diamond—the so-called 'platelets'. This ignorance has now been rectified by G. S. Woods (*Phil. Mag.* **34**, 993–1012; 1976). The platelets (large planar defects on {100} planes) are apparently composed of carbon atoms in interstitial positions (that is, squeezed into the empty interstices between the normal lattice sites).

An anomaly in the X-ray diffraction photographs of some diamonds was first noted by Raman and Nilakantan in 1940. The normal diffraction photograph contains a symmetrical array of spots corresponding to reflection of the X-rays from particular planes of atoms. But in some diamonds—what we now call type Ia—the spots were accompanied by streaks ('spikes'). In 1956 Frank (*Proc. R. Soc. Lond.*, **A237**, 168; 1956) proposed that the streaks were due to planar aggregates of foreign atoms, oriented along the {100} planes—the platelets. His prediction was confirmed by Evans and Phaal in 1962 (*Proc. R. Soc. Lond.* **A270**, 538) when they observed the platelets directly using electron microscopy.

Frank had proposed that the foreign atoms were silicon. Subsequently analyses showed that this element was an uncommon impurity in diamond, whereas concentrations up to $\sim 12\%$ were required to account for the platelets. When Kaiser and Bond (*Phys. Rev.* **115**, 857; 1959) showed that type Ia diamonds contained nitrogen in the required concentration, the obvious conclusion was that the platelets were made of nitrogen—obvious, but wrong.

In 1969 Sobolev, Lisoivan and Lenskaya (*Sov. Phys. Dokl.* **12**, 665) showed that the platelet concentration, as measured by the X-ray spike intensity, did not correlate with the total nitrogen concentration as measured by the infrared absorption peak at $7.8\ \mu m$. The platelets could contain little if any nitrogen.

These results, though controversial, were soon confirmed by a completely independent technique—thermal conductivity. The way the thermal conductivity of a crystal varies with temperature depends on the size and concentration of any defects in it. Turk and Klemens (*Phys. Rev.* **B9**, 4422,



Cathodoluminescence pattern from a diamond. The 'giant' platelets are individually resolvable as white dots in the arrowed band.

1974) showed by this method that at least 97% of the nitrogen in the diamonds they studied was present in aggregates smaller than one nanometre in diameter. No more than 5% could be in the platelets, which are typically 50 nm across.

So what could the platelets be made of? Diamonds had been analysed by many different techniques and no other impurity had been found in anything like the proportions necessary. Evans (*Diamond Res.* page 6, 1973) therefore proposed that they were carbon atoms; but carbon atoms arranged in such a way as to break the normal periodic stacking sequence of the diamond lattice—a plane of interstitial carbon atoms. Woods's paper confirms Evans's hypothesis.

Woods managed to find diamonds containing 'giant' platelets up to 5,000 nm in diameter (see diagram) which he then studied by electron microscopy. He confirmed that these were just large examples of the normal platelets by observing in one of his specimens a continuous gradation in size, down to the more usual 50 nm. Accompanying the giant platelets were loops of perfect dislocation, of interstitial character (like the platelets), and also lying in {100} planes. Their shapes, dimensions and geometries were so unusual, and so similar to the platelets, that Woods concluded they were produced by the platelets. (The alternative possibility, that they produced the platelets, seemed unlikely because the platelets were sometimes present when the loops were not, whereas the converse was never observed). Some of the dislocation loops were L-shaped—they changed from one to another non-parallel {100} plane. Woods therefore proposed that they were created by the interaction of two perpendicular platelets. When the two grew large enough to touch, or came sufficiently close to feel each others' strain fields, two dislocation loops would be created (or a single L-shaped loop if the two loops were in contact). The crucially important point is that, given the geometry of the platelets, of the loops, and of the diamond lattice, and bearing in mind that the platelets are interstitial in character, the platelets can create the loops only if the platelets themselves are composed of carbon atoms in interstitial sites.

If Woods's interpretation is correct —and it is certainly consistent with all the extant data—then he has solved a puzzle that has fascinated diamond physicists for years.

As usual, however, there are questions that are still unanswered. Why is it that platelets are seen only in diamonds containing nitrogen aggregates? Are the platelets formed by interstitial nitrogen atoms displacing substitutional carbon, as Evans suggested? How exactly do the platelet atoms bond to the rest of the lattice? Why are platelets never seen in synthetic diamonds containing nitrogen? Do the platelets play any part in diamond synthesis, or are they merely the product of ageing in diamonds containing nitrogen? Woods's paper is likely to stimulate new thinking on all these questions. □

Exploiting exotic plants

from Robert M. May

ALTHOUGH more than 3,000 plant species have been utilised by man for food, only about 20 major crops today provide food for most of the world.

Motivated by the thought that "to help feed, clothe, and house a rapidly increasing world population, it is timely to consider neglected or little-known plant species", a panel of the National Research Council of the US National Academy of Sciences has presented a report on *Underexploited Tropical Plants with Promising Economic Value* (published by the Board on Science and Technology for International Development, NRC, 1975: see also the excellent summary by Langford, *NAS News Report*, **26** (8), 1; 1976).

The report begins by noting that, in tropical countries, concentration on a small number of major food crops stems not from their inherent superiority, but rather from historical accident. "Many indigenous species may possess equal merit, but were disregarded during the colonial era when consumer demands in European countries largely determined the cultivation (and research) priorities in tropical agriculture". In addition, "most agricultural scientists are unaware of the scope and potential offered by tropical botany. The discipline suffers largely because the major centres of scientific research are located in temperate zones" (NRC, *op. cit.*).

Reliance on a small number of plant species carries risk, because monocultures are vulnerable to catastrophic failure brought about by disease or climatic fluctuations. But, due to the sprawl of cities, the high cost of maintaining botanic gardens and habitat reserves, and the spread of conventional agriculture, potentially useful plants (including varieties necessary for genetic diversity in the development of new food crops) are being destroyed, and some are "in imminent danger of extinction". In urgently recommending programmes of systematic collection and study of tropical flora, the NRC panel hopes that many underexploited plants may thereby follow the example set by the soybean, which has become a staple in many parts of the world only within the past 50 years.

The report describes 36 plants, selected from among 400 nominated by plant experts in many countries. For each of these 36, the report indicates the advantages and limitations of the plant, and outlines special requirements and research needs.

A prime example is quinua. This tall, hardy herb of the Andean altiplano was a staple in the Inca empire. Its grain is rich in protein, with a good balance of amino acids; it is possibly a better protein source than most of the true cereals. Its disadvantage is a bitter taste, derived from saponins in the outer seed layer. The sort of questions that arise for quinua are fairly typical: can it be grown at lower altitudes and in warmer climates; can a satisfactorily saponin-free variety be produced; or should the saponin be retained as a natural defence against pests, and be milled out after harvesting?

A native palm of the Amazon region, *Jessenia polycarpa*, bears fruit clusters from which can be extracted a food oil akin to olive oil. None of the several *Jessenia* species has been cultivated commercially. To quote Langford, "that no one knows how many years are required for *Jessenia* to mature and bear seed indicates the extent of research needs pertaining to many tropical plants".

Naranjilla, "the golden fruit of the Andes", is little known outside Colombia and Equador, where it is used to flavour confections and preserves, and to make a popular fruit drink. The plant could apparently flourish, and be put to these uses, throughout the African and Asian tropics.

In Chile's salt-covered Atacama desert, the leguminous plant tamarugo not merely survives, but can sustain grazing sheep at a density approaching that for green pasture. The report observes that since 1968 more than 5,000 sheep have been raised on tamarugo plantations, and recommends that trials be undertaken in other parts of Latin America, the Middle East, and in arid Africa.

Turning from food and forage crops, the report discusses, for example, guayule. This desert shrub, found in Mexico and the southwestern USA, produces a latex which, when refined, is similar to the rubber obtained from *Hevea* trees in southeast Asia.

The report emphasises that all such

novel plants should be seen as complements to, not as substitutes for, conventional tropical crops. It also acknowledges that the problems of exploiting new plants are not just horticultural, but are economic and sociological: new crops depend on the creation of new markets. ☐

Nucleon coalescence

from P. E. Hodgson

RECENT experiments on the interaction of relativistic heavy ions with silver and uranium have provided evidence that the emitted nucleons tend to stick together to form composite particles, so that the numbers of high energy ^{3}He and ^{4}He particles are two or three orders of magnitude greater than those found for proton-induced reactions at comparable velocities. It was found that more ^{3}He were emitted than ^{4}He, and this made it doubtful whether both their emission could be explained by the same process.

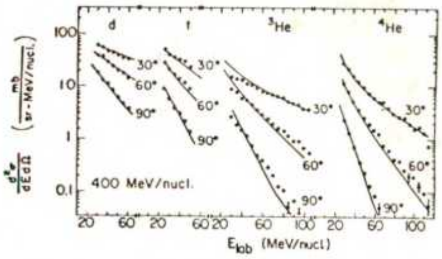
To study this matter in more detail, Gutbrod and colleagues (*Phys. Rev. Lett.*, **37**, 667; 1976) have measured the energy spectra at several angles of the protons, deuterons, tritons, helions (^{3}He) and alpha particles (^{4}He) emitted when uranium is bombarded with 250, 400 and 2,100 MeV per nucleon ^{20}Ne ions and with 400 MeV per nucleon alpha particles, and some typical results are shown in the figure.

To try to account for these distributions, they developed a theory that had already been used by Butler and Pearson to explain the observation of high energy deuterons emitted from nuclei bombarded with energetic protons. This theory assumes that among the cascade of nucleons emitted from such reactions there will be some neutron–proton pairs with rather low relative momenta. The nucleons of each pair can interact with each other and with the surrounding nuclear field to form a deuteron, the nuclear field serving to absorb excess energy and momenta. This model enables the energy spectra of the deuterons to be calculated from that of the cascade nucleons.

The theory was modified to calculate the spectra of the lighter particles emitted from relativistic heavy ion collisions, and the results are compared in the figure with the experimental data. It is seen that the overall features are accounted for very well.

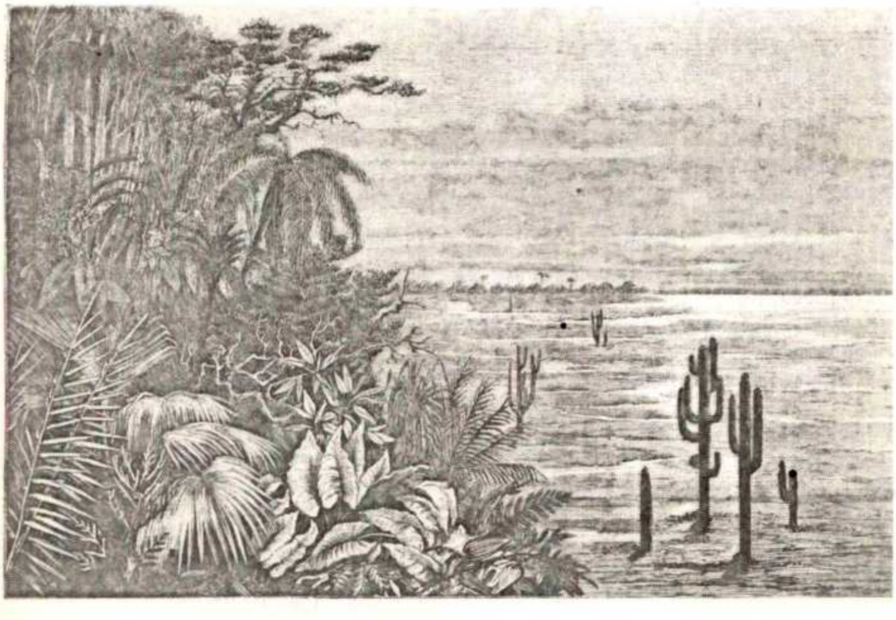
An important parameter of the theory is the greatest relative momentum between the neutron and the proton for which they can coalesce. This momentum was adjusted for each of the reactions investigated so as to give the best overall fit to the experimental data, and it was found that the best values were around 130 MeV/*c* in each case. This constancy checks the validity of the theory.

It still remains to understand the details of the mechanism of nucleon coalescence, but it is certainly encouraging that a relatively simple theory can account so well for so much experimental data relating to very complicated reactions.



Experimental energy spectra of the deuterons (d), tritons (t), helions (^{3}He) and alpha particles (^{4}He) emitted from uranium irradiated by ^{20}Ne ions at 400 MeV per nucleon.

A hundred years ago



TROPICAL FORESTS IN HAMPSHIRE. The Valley of the Bourne restored to represent the conditions which are supposed to have existed during the deposition of the Lower Bagshot Formation: Looking at the scene from a southern standpoint we should see to the north the distant chalk range. Whilst along the shore of the opposite bank of the valley we could with some difficulty detect the various forms of vegetation, which we should see with greater clearness in the more immediate foreground. In this valley a singular stillness must have prevailed, as no trace of animal life whatever has been found, except a feather and a few insect wings blown in from the southern bank.

Of the following at least we are pretty sure, and of numerous others we can be almost sure, but there are indications of very many besides, the relationships of which are at present but imperfectly defined.

Here we should see the graceful fan-palm and the feather palms, adding softness to the view by their elegantly-curved and drooping leaves, laurel and dwarfed oak, stately beeches, clumps of feathery acacia, trellised and festooned with smilax, the trailing aroid, with its large and glossy foliage and an undergrowth of *Mimosa* and of cypress in the swampier ground, and variations in colour caused by the foliage of cinnamon and fig, and the ground clothed with ferns and sedges. On the barren sands of the distant valley are growing clumps of giant and weird-looking cactus. It is not difficult to picture to ourselves the view.

All this beauty is gone. We have nothing but these records of what must have been a view of great loveliness, which only the toil of the geologist can even faintly reproduce.

From *Nature*, **15**, January 18, 261; 1877.

review article

Homoeotic genes, compartments and cell determination in *Drosophila*

Gines Morata† & Peter A. Lawrence

Normal development of Drosophila *depends on the activity of certain 'master' genes. We review recent work which suggests that these genes control the developmental pathways taken by specific groups of cells as they divide and construct precisely defined parts of the adult fly.*

EVERYDAY experience tells us that the form of an adult animal is defined in great detail by its genotype. An example is an individual human face which, although each half develops separately, displays almost perfect bilateral symmetry. Yet how genes determine detailed structure, shape and size is unknown. We know more about the genetics of *Drosophila* than any other multicellular animal and yet even here we do not understand how genes control the development of any organ. If we want to unravel the genetic logic of development we could start with *Drosophila* and try to classify genes into those with a controlling role and those with a more subsidiary executive function.

The best candidates for controlling elements are the so-called homoeotic genes. Mutations in these genes characteristically transform one body part into another. They are particularly well studied in *Drosophila* but they have been found in some other insects[1,2]. In essence the homoeotic transformations are replacements of normal structures by other normal structures which in wild-type flies are found elsewhere. The mutant *bithorax* is a good example of a homoeotic transformation; wildtype flies have a pair of wings and a pair of halteres (Fig. 1) but mutations in the *bithorax* gene[3] transform the anterior half of the haltere into anterior wing. The wing tissue formed in the haltere in these mutant flies is very similar in all respects to normal wing tissue. The wild-type function specified by the *bithorax* gene is thus required during growth of the anterior cells of the haltere; if the function fails these cells will develop as in a wing. The mere existence of such a mutation indicates that there is at least one moment in normal development of the haltere in which the alternative—haltere or wing—is open. In this feature lies the current interest in homoeotic genes; they are single loci which determine the developmental pathways taken by groups of cells.

It has recently been discovered, in *Drosophila*, that special groups of cells are set aside at early stages of development, and that the cellular descendants of these groups form specific regions in the adult called 'compartments'[4,5]. In this review we discuss the evidence that the development of compartments is under the control of homoeotic genes, and highlight the relationship between this new hypothesis[4], and the older concept of cell determination. Since one might expect similar types of genetic control of development in different groups of multicellular animals, we also briefly consider whether these phenomena occur in vertebrates.

In *Drosophila* the cuticular parts of the adult fly are constructed during the pupal period, from a set of 'imaginal disks' which form in the embryo and grow during the three larval stages: for example the wing imaginal disk forms the wing itself as well as those dorsal thoracic parts belonging to the wing segment. Most of the homoeotic mutants produce intersegmental transformations, the structures formed normally being found in another disk. Thus the *bithorax* mutation transforms the haltere segment into part of the wing segment (Fig. 1), *spineless-aristapedia* transforms the antenna into leg (Fig. 1), and *opthalmoptera*, the eye into wing. There are at least two mutants that produce intrasegmental transformations where one part of the disk is the duplication of a different part of the same disk: the mutation *engrailed* transforms the posterior structures of wings into the corresponding anterior structures[6] (Fig. 1). In *wingless* flies the wings are replaced by a mirror image duplication of the dorsal thorax[7,8].

In those cases where homoeotic mutations affect more than one disk they produce homologous transformations in different disks. For example, in *engrailed* posterior wing is transformed into anterior wing, posterior leg into anterior leg, and, probably, posterior haltere into anterior haltere. *bithorax* transforms not only the anterior haltere into anterior wing, but also, the anterior parts of the legs of the haltere segment into the anterior parts of the legs of the wing segment. Clearly there is a common requirement for the wild-type product of the *bithorax* gene in these two regions of the haltere segment, even though the cuticular structures produced by these two groups of cells are distinct. By contrast the type of cuticle in the anterior haltere is almost indistinguishable from that of the posterior haltere, yet the anterior disk cells which form the haltere are sensitive to the *bithorax* mutation while the posterior disk cells are not. Thus the function of homoeotic genes seems to be localised to particular regions of the body.

We need to define as exactly as possible the realms of action of the homoeotic genes. Unfortunately most mutations produce transformations with variable penetrance (penetrance = percentage of the mutant flies which show the phenotypic trait) and variable expressivity (expressivity = degree to which the mutant phenotype is shown by a given fly) which makes it difficult to define the limit of activity of the wild-type genes. Moreover, the expressivity

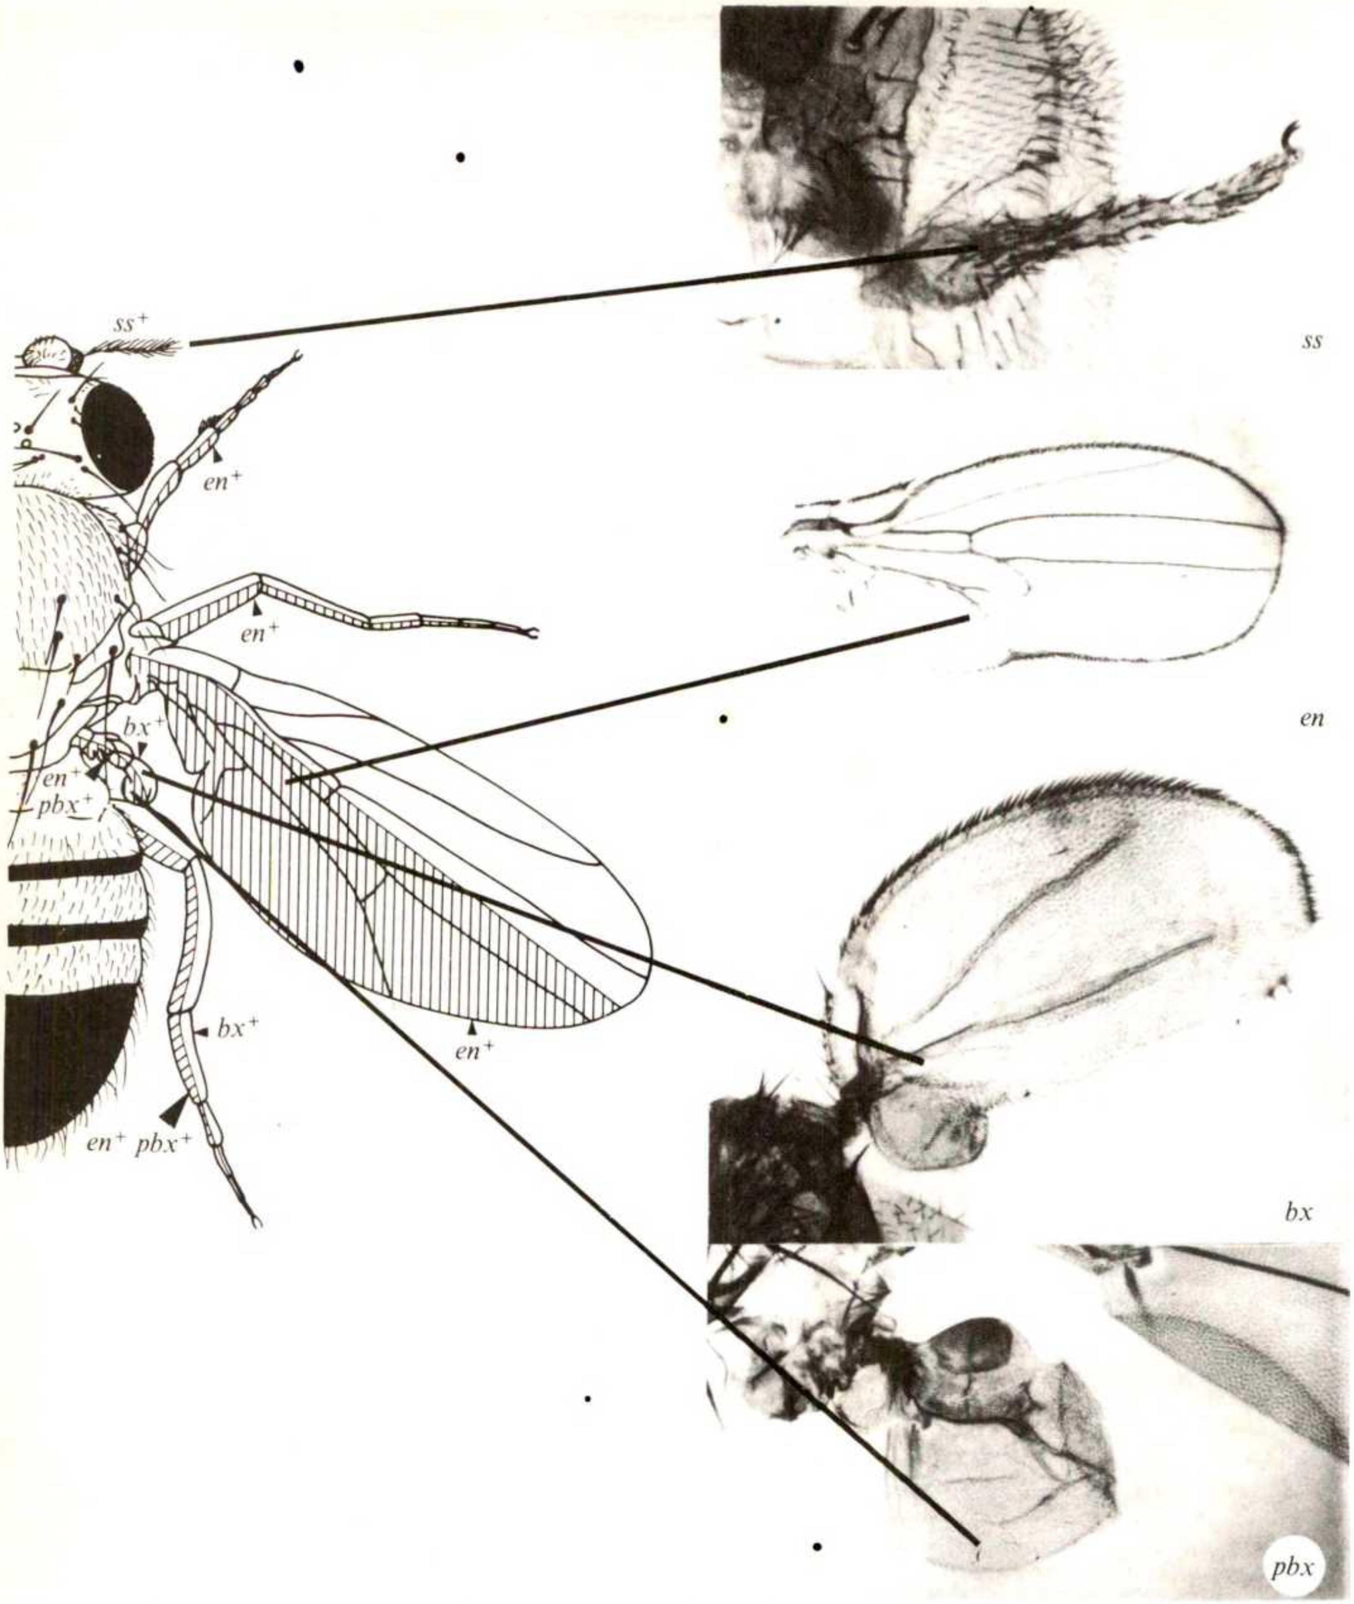

Fig 1. Homoeotic transformations produced by the mutants *spineless-aristapedia* (*ss*), *engrailed* (*en*), *bithorax* (*bx*) and *postbithorax* (*pbx*). A diagram of a wild-type fly is on the left. On the right there are photographs of some of the transformations produced by these mutants. *ss*: The antenna is transformed into leg. Mutations in this locus produce an effect in the antenna only. *en*: the posterior wing is partially transformed into anterior wing as witnessed by the effects on the veins[6,17] and the posterior row of "anterior" bristles. This mutation also transforms the posterior legs into anterior and, probably, posterior haltere into anterior haltere. Consequently the activity of en^+ is required in the posterior regions of at least these structures (shaded in the diagram of the wild-type fly). *bx*: the anterior haltere is transformed into anterior wing and also the anterior III leg is transformed into anterior II leg (this transformation can be recognised because the II and III legs are not identical, each having distinctive cuticular markers). The genotype of the transformation shown in the picture is $bx^3/Df(3R)bxd^{100}$ where $Df(3R)bxd^{100}$ is a chromosome in which the *bithorax* gene is deleted[15]. For this reason the phenotype is very extreme. Notice the sharp boundary between the transformed anterior wing and the unaffected posterior haltere. Only the anterior haltere and anterior III leg require the activity of bx^+. *pbx*: The posterior haltere is transformed into posterior wing and also the posterior III leg is transformed into posterior II leg (as in the *bx* transformation this can also be recognised by cuticular markers). The genotype of the transformation shown in the picture is $pbx/Dp(3;3)bdx^{100}\ Df(3R)P115$ where $Dp(3;3)bxd^{100}\ Df(3R)P115$ is a chromosome in which the *postbithorax* gene is deleted[15]. For this reason the phenotype is very extreme. Notice again the sharp boundary between the unaffected anterior haltere and the transformed posterior wing. Only the posterior haltere and the posterior III leg require the activity of pbx^+.

of some of those mutants varies greatly in different regions of the same disk[9]. The probable reason for these incomplete transformations is that the mutants are leaky (*hypomorphs* in the *Drosophila* terminology) in which some wild-type function remains. Mutants like *Antennapedia* of *Rappaport* (Ant^R) produce a partial transformation of arista and antenna into leg so that the final structure is a mixture of phenotypically wild-type (arista or antenna) and mutant (leg) cells[10]. This is also the case for other mutants such as the different alleles of *spineless-aristapedia*[11] and *opthalmoptera*[12] and some *bithorax* alleles. According to the description of *Antennapedia*[10], it only affects the antenna part of the eye-antenna disk (even some antennal disk derivatives like rostralhaut and maxillary palpus are not affected) whereas *Nasobemia* which is probably in the same locus[13] very often transforms part of the head cuticle belonging to the eye part of the disk[14]. It is conceivable that a very extreme *Antennapedia* mutation could transform the eye and perhaps other structures as well. For these reasons all homoeotic genes should ideally be studied with mutations that completely lack wildtype function—for instance with chromosomes that are deficient for the gene itself. Unfortunately this is usually impractical; the deficiencies are nearly always lethal when homozygous (we know that most deficiencies, even the smallest ones, are lethal[15]) and one has to be satisfied with the viable mutants that are most extreme. Even this is difficult, because too few mutant alleles are available (for example, there is only one allele of *engrailed*)—perhaps because homoeotic genes frequently mutate to a lethal form. For *bithorax*, where there are many alleles, a detailed genetic analysis has been done by Lewis[3,16,17]. The mutation bx^3 is the most extreme known[16]; homozygous bx^3/bx^3 flies show a phenotype only slightly less extreme than bx^3/bx^- (where bx^- is the deficiency of the gene) which indicates that bx^3 almost completely lacks function of the *bithorax* gene. Thus in this case we can be reasonably certain that the extent of the phenotype bx^3/bx^- defines the domain affected by the *bithorax* gene.

We clearly need much more genetic analysis of homoeotic mutants, and new methods are now being developed: although some 90% of induced mutations in *Drosophila* are lethal[18], only about 20% of these are cell lethal[19]—the phenotype of those lethal mutants that are viable in individual cells can be studied in clones made homozygous for the mutation[20].

Determination in mature disks

The concept of determination in the imaginal disks of *Drosophila* has been developed by Hadorn and his associates[21] and discussed in detail elsewhere[22]. It refers to the acquisition by a group of cells of a commitment that precisely defines the fate of their descendants. Unlike many other developmental systems, the imaginal disks of *Drosophila* show a clear distinction between determined and differentiated state; one can demonstrate that the imaginal disks are determined to secrete certain regions of the adult cuticle much before this differentiation starts. An imaginal disk or a fragment of imaginal disk is considered to be determined if, when transplanted into the abdomen of a host larva, it differentiates autonomously into the same structures as *in situ*. When this type of experiment is performed on the mature imaginal disks it is found that they are strictly determined; the wing disk only and always forms wing structures, the first leg disk only forms first leg structures and so on. Their state of determination is more restricted than just leg or wing; within one disk, particular regions, when explanted, form specific parts of the adult structures, and in this way consistent fate maps of the mature disks have been constructed[23,24] and in some cases even individual bristles have been located precisely in the disk[25].

The acquisition of a given state of determination seems to correlate with the ability of determined cells to recognise, and associate with, like cells and dissociate from unlike cells[26]. Cells from a given disk or disk-fragment, after dissociation and mixing, remain mixed together and form integrated patterns of differentiated structures. However, cells from different disks or different regions of the same disk will sort out from each other and form separate patterns. In these experiments each type of cell differentiates autonomously according to its disk of origin[26,27].

We have no direct criterion for determination—the term is a purely operational one; determination may be stable in some experimental conditions but unstable in others. Thus, if imaginal disks are cut and the fragments allowed to grow in *in vivo* culture for several days or more, the state of determination can change. For example, groups of cells[28] in growing fragments of leg disks will frequently 'transdetermine' to other cuticular structures such as wing[23,29]. Even the stability of determination of a given fragment depends on the precise experimental conditions: thoracic fragments of the wing disk will only make thorax after extra growth, but if mixed with wing fragments they make both thorax and wings[30]. For these reasons experiments involving a long period of extra growth in *in vivo* culture cannot be used to deduce the state of determination that the initial fragment had *in situ*.

Determination in development

Determination probably begins at around the blastoderm period; if blastoderm cells are dissociated and mixed they will reaggregate specifically with cells that come from the same region of the egg[31]. If individual anterior blastoderm cells are transplanted to the posterior pole of the egg, they will not integrate with the foreign blastoderm cells, and will differentiate anterior structures in the adult[32].

Clonal analysis is a powerful technique which has been applied to early development and can help to pinpoint the establishment of determination. Use is made of cell marker mutants which alter the colour of the cuticle or the shape of bristles in the adult fly but apparently do not affect the course of development. Staged eggs or larvae heterozygous for such a mutant are irradiated with X-rays. At low frequency, somatic recombination occurs in a cell so that one of its daughters becomes homozygous for the mutant, and generates a clone of cells of different genotype. After metamorphosis this clone is seen as a patch of marked cuticle on the adult. This method provides another criterion for determination, if mainly a negative one; when two structures are included in the same clone it shows that the original marked cell was not determined exclusively for either[22]. However, if two structures are never included in the same clone, it does not necessarily mean that their ancestor cells were determined differently. One must then show that the clones are large enough for at least some of them to have included the two structures and also that no physical barrier separates those structures in normal development.

In a careful analysis of early development of imaginal disks, it has been shown that clones produced by irradiation of the embryo at the time of cellular blastoderm can comprise structures of wing and second leg (both belong to the mesothoracic segment) proving that at that time the cells are not exclusively determined for either[33-35]. Clones do not cross from one segment to another, suggesting that the segments are determined[33-35]. Clones produced a few hours later were restricted to either second leg or wing[33]. These results certainly indicate the appearance of a developmental segregation between ancestral cells for wing and leg in early development. Indeed, histological studies in another dipteran, *Dacus*, have shown that there is an initial group of cells of the mesothoracic segment that later become subdivided into dorsal (wing) and ventral (leg) imaginal disks[36].

Other evidence suggesting early determination comes from experiments in which homoeotic transformations are produced by chemical or heat treatment[37,38]; such changes are called phenocopies. For example, when early embryos are treated with ether as many as 30% of the flies show *bithorax* phenocopies[37,38]. They do not look exactly like flies mutant for *bithorax* because only part of the haltere is transformed into wing. These changes can be produced only at or around the blastoderm period[37,38], suggesting that the phenocopying agent interferes with some determinative process that takes place at that stage[38].

This evidence from clonal analysis and phenocopies does not tell us when imaginal disks are determined; in neither case has the total extent of the marked or transformed tissue been defined and it could include internal or larval organs. As individual disks appear as identifiable structures at late embryonic stages[39,40] they are probably determined by that time.

Determination and homoeotic genes

By the criteria usually used to define the state of determination, the homoeotic mutants change it. For example, antennal disks of *spineless-aristapedia* differentiate leg structures when transplanted into metamorphosing larvae[11]. In experiments where genetically marked cells from two different imaginal disks are dissociated, mixed together, and allowed to grow in an adult abdomen they usually sort out from one another[26,27]. While wild-type antennal and leg disk cells will segregate from each other, antennal disk cells from flies mutant for *spineless-aristapedia* will mix with wild-type leg disk cells[41]. In similar experiments, mutant haltere disks for *bithorax* differentiate wing structures in isolation and their cells will mix with wild-type wing cells[41,42]. Thus, by these criteria, the state of determination of the antennal disk is changed by *spineless-aristapedia* into that of the leg and the state of determination of the haltere is changed by *bithorax* into that of the wing. It follows that the normal function of homoeotic genes is necessary for the normal process of determination.

Since the disks become determined in early development, it is expected that the homoeotic genes will function early in development. There is some evidence that they do. In flies homozygous for extreme *bithorax* and *postbithorax* combinations (which transform the entire haltere into a complete wing, see cover), the number of cells of the mutant haltere disk is 2–4 times larger than the wild-type haltere disk in the first larval period and equal or similar to that of the wild-type wing disk[43]. This result indicates that the mutant phenotype is already expressed by the first larval period and therefore that the wild-type gene has already been required.

There are several experiments which indicate that there is, as well, a late requirement for the *bithorax* gene. When *bithorax* clones are produced in a wild-type haltere, the clones show mutant phenotype[4,43] (that is, they produce wing structures) even if they are induced before the end of the third larval period[43]. Only when the clones are produced in the late third stage larva do they fail to show mutant phenotype[43]. As we discuss below, the gene product may still be required after that time. A similar conclusion is indicated by some temperature sensitive alleles of *bithorax* where experiments have located the phenocritical phase in the third larval period[44]. Clearly, the activity of the *bithorax* gene is required until late in development of the third instar, but not thereafter. This ability of wild-type phenotype to persist in the absence of wild-type genes has been described for certain mutants affecting bristles, and called *perdurance*[45]. Although other explanations are possible, the simplest is that perdurance is the persistence in mutant cells of some wild-type function which is not diluted out in the last few cell divisions before the disk stops growing. This view is supported by the observation that late *bithorax* clones that show perdurance *in situ* (that is wild-type phenotype), differentiate mutant phenotype after additional growth in culture *in vivo* (Garcia-Bellido, unpublished). We have seen that there is evidence for *bithorax* function in the first stage larva, and that it is needed until metomorphosis. It seems likely, therefore, that the gene is active throughout most of larval development, and perhaps in the embryo as well (see ref. 43 for discussion).

Although the preceding discussion relies heavily on data on *bithorax* mutants, observations on other homoeotic mutants point to similar conclusions: there is evidence that the *engrailed* gene is required throughout most of the larval period for normal development of the cells of the posterior wing[6,46]. Its activity stops intermingling of anterior and posterior wing cells[46,47]. Indeed, as the anterior and posterior cells are first segregated at the blastoderm stage[34,35] but may lie adjacent to one another[48,35] the *engrailed* gene is probably required then. Mitotic recombination[6,47] and temperature shift experiments[47] show that wild-type function of the *engrailed* gene is required until the late third larval period. Mutant *spineless-aristapedia*, (ss^{a}), clones produced earlier than the mid-third larval period in a wild-type antenna show mutant phenotype (leg structures) but they retain wild-type phenotype when induced in the late third stage larva[49]. Also, the cold-sensitive allele ss^{a40a} has a phenocritical period in the third larval stage[50,51]. Both these observations are most simply explained as perdurance effects. Thus the *bithorax*, *engrailed* and *spineless-aristapedia* genes probably have a similar mode of action; they are responsible for the expression of specific states of determination by groups of cells. Specific disk cells require a continuous supply of the wild-type product of these homoeotic genes for the maintenance of their state of determination. If the activity of the homoeotic genes fails, the state of determination changes accordingly.

It now becomes easier to understand the instability of the state of determination in some hypomorphic (leaky) mutations like *Antennapedia* of *Rappaport*[10] or *Contrabithorax*[9]. In the first case the mutant antenna is a mixture of leg and antenna cells and in the second case the mutant wing is a mixture of wing and haltere cells. When clones homozygous for genetic markers are produced in the mutant appendages, it is found that even clones produced in the third instar can comprise leg and antenna in the case of *Antennapedia* and haltere and wing in the case of *Contrabithorax*. These experiments indicate that the decision whether to make one or another type of structure is not inherited through cell divisions but is made very late in development. Although these results have been interpreted as evidence for late determination in the mutant disks[10] they probably instead reflect the inherently unstable state of determination of the mutant cells that can change according to the amount of wild-type product present in each cell. Even during *in vivo* culture the homoeotic genes and their products are still required: *spineless-aristapedia* 40a has a phenocritical phase in the middle of the third larval period[50,51]. Mature antennal disks from the late third instar have passed the phenocritical period and have a strict state of determination which is independent of the temperature. However, if these same disks are cultured *in vivo*, the cells produced during the period of extra growth can become determined differently according to the temperature in which they grow[51].

Compartments and homoeotic genes

Clonal analysis of imaginal disks of *Drosophila* and the abdomen of the milkweed bug, *Oncopeltus*, have shown that there are certain boundary lines in the adult cuticle which are not crossed by clones after a given moment in development[52–55]. In *Drosophila* the introduction of the Minute technique[4,56] allows the production of marked clones that grow more rapidly than surrounding cells and reach a very large size. These clones can nearly fill certain regions

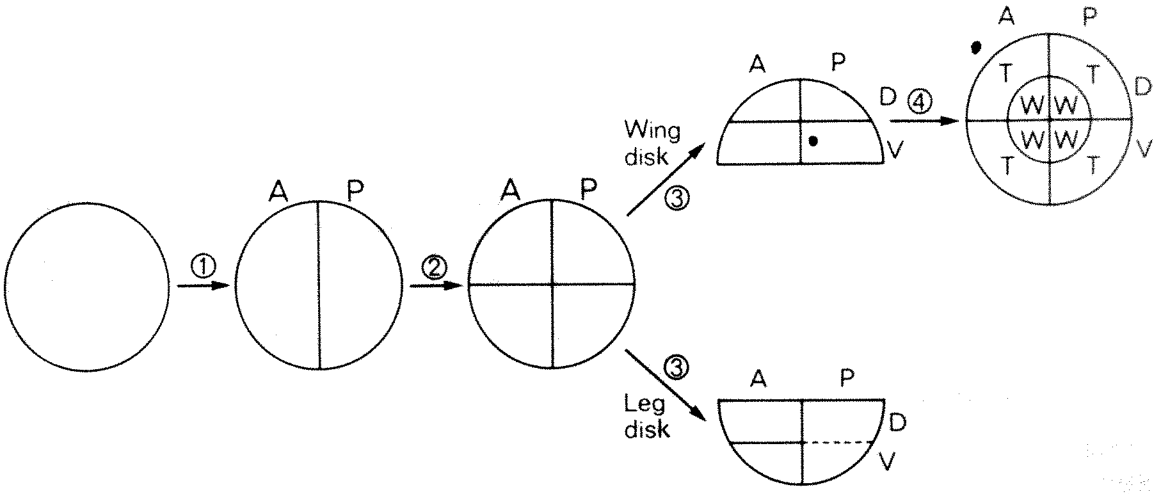

Fig. 2 Diagram of compartmentalisation of the mesothoracic cuticular structures. After each subdivision (represented by a straight line) no clone can include territories on both sides of that line. The first step (1) is the segregation of anterior (A) and posterior (P) polyclones, and this occurs, probably, at the blastoderm stage. The second (2) consists of the separation of the dorsal part of the segment (wing disk) and the ventral part (leg disk). This event takes place before 10 hours of development. These two disks later become physically separated. During the larval period the wing disk becomes subdivided (3) into wing dorsal (D) and wing ventral (V) and about the same time (4) into thorax (T) and wing blade (W). For the leg disk there is some evidence[34] of the subdivision of the anterior compartment into dorsal and ventral.

of the cuticle which are defined by precise boundaries in the adult. These regions are called compartments[4,5]. They are constructed by all the descendants of a particular group of founding cells (a polyclone[57]) which is set aside at an early stage of development. It has been shown that dividing cells cannot cross certain boundaries, and that some of these become effective before others[4,5], so that there is a successive subdivision of polyclones into daughter polyclones. In the cases studied so far the number of cells in the founding polyclones is small, being between 5–50 (refs 53, 54, 58–60, 61).

The assignment of a cell to a given polyclone is a stable developmental commitment; all the cell's progeny will be constrained to form structures within one specific compartment. In this way development can be visualised as a process in which homogeneous populations of cells are split into subpopulations with different developmental potential.

In *Drosophila* the formation of compartments has been studied for several imaginal disks[4,5,34] and has been reviewed recently[57,62]. Here we will discuss mainly the relationship between compartments, homoeotic genes and determination.

For the wing disk there are at least three subdivisions that produce eight major compartments. The wing is first subdivided into anterior and posterior regions and each subdivided further into dorsal, ventral, wing blade, and thoracic parts (Fig. 2). The first subdivision occurs so early that the mesothoracic disks (wing and second pair of legs) are subdivided into anterior and posterior polyclones before the wing-leg segregation occurs[34,35]. This is shown by clones produced about the blastoderm stage of embryonic development which include both anterior wing and anterior second leg structures or posterior wing and posterior leg. No clone has been found to transgress the antero-posterior compartment boundary in either leg or wing[34,35]. This observation shows that compartmentalisation begins before individual disks are formed. It is the whole mesothoracic polyclone (which forms the cuticle and perhaps other internal tissues as well) that becomes subdivided into anterior and posterior polyclones. The progeny cells of these anterior and posterior primordial polyclones will include all the anterior (leg and wing) and posterior (leg and wing) cuticular structures respectively. The probable sequence of compartmentalisation in the mesothorax is shown in Fig. 2.

An important feature of the antero–posterior compartment boundary is that it apparently defines the limit of function of certain homoeotic genes[4,5,46,47]. This is the case for the haltere-wing transformations produced by the *bithorax* and *postbithorax* mutants (both members of the *bithorax* pseudoallelic series[3]). The anterior wing structures produced by bx^3/bx^- (Fig. 1) in the haltere disk correspond to those defined in the ordinary wing by the antero-posterior compartment boundary, and the posterior wing structures produced by pbx/pbx^- correspond to the posterior ones defined in the normal wing by the same boundary. Thus *bithorax* and *postbithorax* have an effect on specific polyclones so that entire compartments are transformed. The same boundary is also recognised by the mutation *engrailed*. The activity of the wild-type function of *engrailed* is required by posterior wing disk cells: without it, these cells fail to develop both a normal posterior compartment and a normal antero–posterior compartment boundary[6,46,47].

Of other compartment boundaries described for the wing disk, the one separating proximal (thoracic) from distal (wing) structures seems to be the limit of the transformation produced by *wingless*. This mutation produces a duplication of the thoracic structures while the wing disappears[7]. As it affects the haltere disk in a homologous manner, the *wingless* gene may be involved in the development of the distal compartments of both the wing and haltere disks[8].

Determination begins when the original founder cells of the polyclone are chosen. Thereafter, during normal development, the cells of the polyclone can only form parts of a restricted region in the adult—the compartment. One would like to dissect the determinative process down to its operational elements, and some hints come from mutants like *engrailed* which produce duplicated compartments within one disk. It would seem that the subdivision of the polyclone into two sub-polyclones has proceeded normally, even though the homoeotic gene is defective. This suggests that, in normal development, there are at least two separable elements in each determinative step: (1) the definition of groups of cells and (2) the permanent activation of a homoeotic "selector gene"[62] in one or more groups. Garcia-Bellido[62] has coined the term selector gene to emphasise that there may well be more than one class of homoeotic mutation: homoeotic changes could result from mutations which affect the subdivision of polyclones, the genetic machinery leading to the activation of a particular homoeotic selector gene, or the selector gene itself.

The choice of particular groups of cells is probably geographic[57] and depends, for example, on polarity and positional information in the egg[63,64] or position in the disk. Homoeotic mutations in genes affecting these processes might be expected to have unusual properties, some might show a maternal effect. The gene products might only be required at an early stage of development, so that clones of cells mutant for these genes produced after that stage might show normal wild-type phenotype, *wingless* is, possibly, an example of such a gene[8].

The selector gene, as exemplified by *bithorax*, is a gene whose product is required continuously throughout development to 'select' a particular developmental pathway[62]. The role of the selector genes is of considerable interest; they seem to control the activities of many other genes which perform executive functions[62]. For example, the cell marker mutants are not restricted to particular compartments and their products are probably required by all cells that secrete cuticle. When the selector gene product is defective or missing all compartments where that selector gene is normally activated will be homoeotically transformed—which explains why single genetic lesions such as *engrailed* can produce homologous transformations in different disks.

Conclusions

At least in some cases, homoeotic mutations transform entire compartments. This indicates that the activity of these genes is restricted to specific polyclones. As we have seen the activity of homoeotic genes is necessary for the expression of certain states of determination. Thus the compartments seem to be the units of determination during normal development, the founding polyclone of a given compartment constituting the initial group of determined cells.

In this view, the final state of determination of the cells belonging to a compartment is the result of a series of events. Every determinative event is accompanied by the activation of a certain selector gene. Some of these events are common to different polyclones, but the combination of them, and therefore the combination of active and inactive selector genes, is unique to each compartment. Determination is a result of genetically controlled commitments made by *groups* of cells and passed on to all their progeny. The effect of each determinative step is conditioned by the previous ones, so that at each moment the cells react according to their developmental history.

Are there compartments and homoeotic genes in vertebrates?

It is not clear whether compartments occur in vertebrate development, and if they do, whether they are similar to those found in insects. The idea of lineage segregation is of course inherent to the germ layer theory, and it has been suggested before that vertebrate organs of one cell type may have their origin in a special group of cells[65]. Moreover, recent studies on early mouse development have shown there is a series of binary decisions, involving small numbers of cells (15-50, ref. 66), each apparently accompanied by changes in cell structure and possibly in cell adhesion, and each resulting in some restriction in developmental potential. For example, the first of these separates the prospective embryonic cells (inner cell mass) from the trophoblast. As in insects[57] these segregations appear to be made geographically[66].

In vertebrates determination has often been thought of as being to a particular cell type, such as muscle or nerve. Yet the picture coming from studies on *Drosophila* is one of commitment to a precise region; that is some kind of area property[57]. In vertebrates, detailed lineage studies could reveal whether a single organ or tissue is subdivided into compartments, but have not yet been undertaken. Other possible correlates of compartmentalisation might give further information. For example, some compartment boundaries in insects appear to be recognised by peripheral nerve axons[67], and a precisely placed line, which is respected by such axons, has been found separating the amphibian limb into two regions[68].

There is a lack of genetic evidence for compartments and homoeotic genes in mammals; this may not be significant since homoeotic mutants are more likely to be viable in insects, like *Drosophila*, where there is a complete metamorphosis and some adult structures (such as wings) are dispensable. These observations are certainly suggestive—even in the absence of detailed studies of cell lineage and the existence of frank homoeotic mutants.

We thank Tom Kornberg for his advice. Gines Morata is supported by an EMBO fellowship.

Configuration of tobacco mosaic virus RNA during virus assembly

P. J. G. Butler, J. T. Finch & D. Zimmern

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

When TMV reassembles, the uncoated RNA is folded back along the growing rod, probably down the central hole. This surprising configuration is essential for rapid elongation—presumably supplying RNA to its site of incorporation while keeping the bulk of the free RNA out of the way.

THE location of the nucleation region for the assembly of tobacco mosaic virus (TMV), from isolated coat protein and RNA, about 1,000 nucleotide residues from the nearer end of the RNA molecule (the 3′-hydroxyl terminus)[1,2] raises questions about the elongation process. Since the RNA is totally enclosed in the mature virus particles, elongation from the original site of nucleation must occur in both directions—towards the 3′- and 5′-hydroxyl termini of the RNA. This presents a paradox in view of the observation[3-7] that partially assembled rods of TMV have RNA tails only at one end, in agreement with the generally accepted view that assembly would be polar. We have shown that the two ends of the TMV rod can be distinguished in the electron microscope because one is convex and the other concave and, taking this together with stripping experiments, we have shown in which direction the RNA runs within the complete nucleoprotein helix[8]. We have now applied this technique to locate the free RNA in the growing nucleoprotein rods.

Preparation of rodlets

Partially assembled rodlets of the desired length range were obtained by allowing an appropriate amount of the protein, supplied as a disk preparation, containing about 80% of the 2-ring disk aggregate[9], to reassemble with the RNA[10] at 20 °C in sodium phosphate buffer, *p*H 7.0, ionic strength 0.1 for 10–15 min[9]. Rods about half the size of complete virus particles were obtained with a protein:RNA ratio of 10:1. Rodlets with free RNA tails at the 5′-hydroxyl end were prepared by partial alkaline stripping as before[8].

Both the rodlet preparations described were contaminated with free protein—either unreacted and possibly damaged in the partially assembled preparation or that which had been stripped off in the partially stripped preparation—and possibly some free RNA. These contaminants were much smaller than the rodlets and were removed before reassembly by centrifugation through sucrose gradients, without allowing the rodlets to pellet, as this alters their reassembly activities[9]. Gradients were prepared in Tris-chloride buffer, *p*H 8.0, ionic strength 0.1, by layering into tubes 2 ml 60% (w/v) surose, 2 ml 40·, 3 ml 20· and 2 ml 5· sucrose. Samples (3 ml) were layered on top and the gradients were centrifuged at 40,000 r.p.m. and 5 °C for 1 h in an MSE 6 × 14-ml titanium swingout rotor. Fractions were collected from the bottom of the tubes and the fractions from the turbid layer were pooled and dialysed against sodium phosphate, *p*H 7.0, ionic strength 0.1 containing 1 mM sodium azide.

The turbid suspensions had spectra characteristic of nucleoprotein, while the fractions from the tops of the gradients gave the spectrum of TMV protein, suggesting that little free RNA was present in the original preparations.

Location of RNA tails on growing rods

Although the uncoated RNA is not as clearly visible at the ends of partially assembled rodlets as on partially stripped rodlets, it can nevertheless be seen on many of the particles and the morphologically distinct ends of these particles can be distinguished. From Fig. 1 it seems that the RNA tails are at opposite ends of the two types of rodlet. This was confirmed by inspecting all the particles in

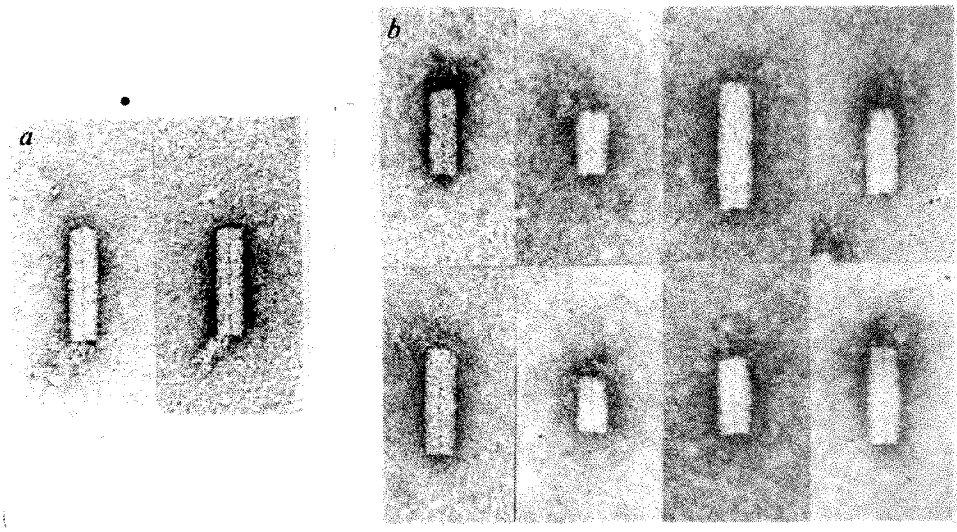

Fig. 1 Electron micrographs of TMV particles: *a*, partially stripped with alkali[8], and *b*, partially reassembled. The images are aligned with the rounded or convex ends at the top and the concave ends at the bottom. The 'puffs' of uncoated RNA can be seen at opposite ends in the two cases (approximately × 170,000). Specimens from the rodlet preparations were prepared by allowing the particles to adsorb on to carbon-coated grids from a drop of solution for about 30 s, followed by rinsing with distilled water and negative staining with 1% (w/v) uranyl acetate. The grids were examined and photographed in a Philips EM 300 electron microscope at a magnification of approximately 25,000.

Table 1 Numbers of particles for which the end with the exposed RNA is morphologically distinguishable

Type of rodlet	End showing RNA Convex	Concave	Both
Partially stripped[8]	1	62	6
Partially assembled	88	4	3

several fields of partially assembled rodlets and assigning the free RNA to the different ends whenever this could be done unambiguously. The counts are shown in Table 1, together with those for rodlets partially stripped by alkali using the same technique[8]. Clearly the RNA tails of the partially assembled rodlets occur at the convex ends of the particles in contrast to the situation found for partially stripped rodlets[8]. (Less than 8% of rodlets, whether single or double tailed, were identified with a tail at the concave end.)

Because TMV RNA is about 6,400 nucleotides long with the nucleation region about 1,000 nucleotides from the 3′-hydroxyl end[1,2] and hence more than 5,000 nucleotides from the 5′ end, the main direction of assembly must be from 3′ to 5′. In partially assembled rodlets the longer tail should therefore contain the 5′ end, which is the end released by alkali stripping[11]. As RNA tails are visible in partially assembled rodlets principally at the ends which contain the 3′ ends of the RNA in the final viruses, the RNA must be folded back on itself in the growing rods because it protrudes only from the end at which least elongation occurs (Fig. 2).

Rates of elongation

We suggest that the looping back of the 5′ end of the RNA in the growing rods, probably down the central hole, is important for the mechanism of elongation of the rods in the dominant direction, from 3′ to 5′. In this case we expected that the rates of elongation of partially assembled rods and of partially stripped rodlets might be different because, although both would be elongating in the 3′ to 5′ direction, the long RNA tail would be tucked down inside the former but protruding from the stripped end of the latter.

This prediction was investigated using rodlets which had been purified and checked in the electron microscope to ensure that most still had RNA tails. Protein for elongation was supplied both as a disk preparation and as A-protein. The results of one such experiment, in which the partially assembled rodlets and two preparations of partially stripped rodlets were purified in parallel, including the final dialysis in the same flask, to eliminate any possible effect of preparative history, are shown in Table 2. Although the large molecular sizes and unknown molecular weights of the preparations make it unsafe to try to calculate the absolute rates of elongation from these rates of increase in turbidity, or even to make a close comparison of the rates between different preparations, the partially assembled rodlets seemed to elongate more than an order of magnitude faster than did the partially stripped rodlets. This conclusion remains, even allowing for the greater concentration of the former.

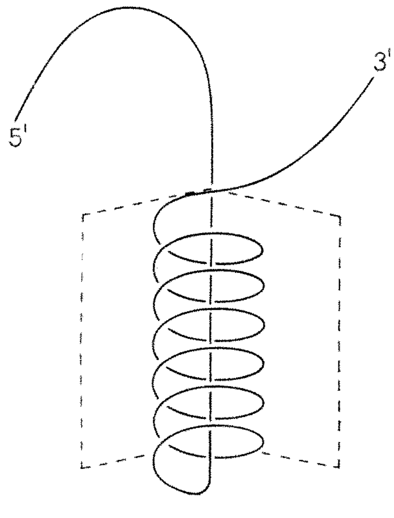

Fig. 2 Schematic picture of the suggested arrangement for the RNA in a growing rod. The dominant direction of assembly (that is, from 3′ to 5′) is downwards—at the end opposite the two RNA tails. The placing of the longer, 5′ tail up the central hole is arbitrary and, while we think this is the most likely configuration, there is no direct proof as to how it reaches the opposite end of the rod.

A compatible result was obtained when the lengths of partially stripped rodlets were compared by electron microscopy before and after incubation with a disk preparation at 1.0 mg ml^{-1} for 30 min. While partially assembled rodlets would, in these conditions, be expected to elongate by 150–200 nm (refs 9,12), the partially stripped rodlets only increased by about 10 nm. Although a ^{2} analysis on the histograms of lengths of the rodlets showed that even without genuine elongation, such and apparent change could have arisen from sampling with a probability of just under 0.1, we think that elongation had taken place, as it has a 90· probability of doing. Moreover, rods partially stripped from the same end with SDS[8] will reassemble over several hours to give nuclease resistant infectivity[13], in agreement with the idea that some slow elongation can probably occur even with the RNA tail free at the abnormal end of the growing rod.

Preliminary location of both tails

The observations of the RNA tails described above were made with negatively stained specimens, so that high resolution electron microscopy distinguished the ends of the rodlets, but in these conditions the RNA tails only appear as 'puffs' and it is not possible to distinguish between one or two tails at the same end of a rod, but rather the major tail (the 5′ end) dominates the image. We have occasionally seen partially assembled particles apparently with two RNA tails coming from the same end, by electron microscopy of specimens shadowed after spraying onto carbon coated grids with only bovine serum albumin as a spreading agent. We do not regard these observations as very significant because most of the particles showed only a single tail, and some free RNA was visible in the background. To obtain better spreading and separation of the tails it is probably necessary to add some denaturing agent. Preliminary experiments, however (unpublished results of B. Jacrot and D.Z.), showed that partially assembled rods are very unstable when RNA is denatured for spreading, although partially stripped rodlets could be visualised. This again shows the difference between these types of rodlet, but emphasises the need for extreme caution in interpreting such data because preparation may significantly alter the specimen.

An alternative approach to visualise and distinguish the ends of the RNA is to label them with a bulky molecule. We have done some preliminary experiments using ferritin, activated for reaction with periodate-oxidised RNA[14] by coupling to carbohydrazide with ethyl dimethylaminopropyl-carbodi-imide[15,16], to label both termini. One problem is that the tendency to form ferritin aggregates could cause confusion. Although we have never seen a particle with ferritin molecules at both ends, we have seen several partially assembled rodlets on which two ferritin molecules appear, in the electron microscope, to be attached to the same RNA 'puff' and yet are too far apart to be attached directly to each

Table 2 Rates of reassembly of partial TMV rodlets

Rodlet preparation	Rate of turbidity increase (D_{310} per min) Disk preparation	A-protein
Partially stripped I	0.00125	0.0006
Partially stripped II	0.00115	0.00065
Partially assembled	0.0316	0.0221

Rodlets were prepared either by partial alkali stripping or by partial reassembly. Elongation in sdium phosphate, *p*H 7.0, ionic strength 0.1 at 20° C, was followed by the increase in turbidity at 310 nm (ref. 9), with either a disk preparation or A-protein added to 1 mg ml^{-1} final concentration. Final rodlet concentrations were 0.20 and 0.195 D_{260} per ml for the partially stripped rodlets I and II and 0.42 D_{260} ml^{-1} for the partially assembled rodlets (corresponding to approximately 0.6, 0.5 and 1.2 mg ml^{-1}, respectively).

other. We believe that this indicates that the two RNA termini are indeed at the same end of the assembling rodlet and we are continuing experiments to confirm this.

Implications for assembly

The structure of the protein disk is known to a resolution of 5Å (ref 17) and consists of two rings, each of 17 protein subunits, stacked on top of each other. While these make a firm contact at high radius, they are separated vertically at the RNA-binding radius, like a pair of 'jaws', and the protein has considerable flexibility inside this radius. These features suggested that the RNA might well be intercalated between the two rings of the disk, during both nucleation and elongation, from the central hole of the disk and in this way the two-layer disk could be incorporated into the single helix.

Although there is no firm evidence of whether the doubling back of the longer RNA tail occurs inside or outside the growing nucleoprotein helix, we suggest that it is probably inside with the RNA strand running freely down the central hole (Fig. 2). This configuration in the growing rod would follow smoothly from a mechanism of nucleation by the insertion of a hairpin loop of RNA into the centre of the first disk[18]. Such a geometry will allow access of the relevant region of the RNA to its binding sites on both rings of an incoming protein disk and yet hold the bulk of this RNA strand well out of the way of the region of activity, greatly facilitating the process of rod elongation.

A model for superlight velocities of extragalactic radio sources

Richard I. Epstein* & Margaret J. Geller

Center for Astrophysics, Harvard College Observatory and Smithsonian Astrophysical Observatory, Cambridge, Massachusetts 02138

An explanation is proposed for apparent superlight velocities of compact radio sources. In our model high velocities are a consequence of the interaction of the radio sources with the ambient gas in a galactic nucleus or quasar. This model predicts that the pair of sources is not centred on the nucleus and that the individual components should be smaller and more separated when observed at higher frequency.

APPARENT faster-than-light velocities of separation have been measured with VLBI for compact double radio sources in 3C120, 3C273, 3C279, and, most recently, in 3C345 (refs. 1-8). Furthermore, in a number of low-frequency sources the time-scale for luminosity changes corresponds to apparent expansion velocities in excess of the speed of light[9].

Many explanations have been offered for these perplexing observational results; however, the models proposed so far either contain implausible assumptions or predict phenomena which have not been observed, such as double sources in which the components move toward each other or in which the components have very dissimilar luminosities[2-7,10-13].

From observations of extended extragalactic radio objects it is known that mechanisms exist for ejecting energy sources in well defined directions from the centres of galaxies and quasars[14,15]. We show here how the motion of one of these energy sources through the ambient gas in the centre of a quasar or galactic nucleus can produce a pair of bright radio emission regions which separate at superlight velocities or can produce rapid luminosity changes. The model we propose thus provides suggestive connections among the observed properties of quasars and galactic nuclei, and extended and compact radio sources. Our model is an extension of the expanding radio source models of Shklovskii[16,17] and van der Laan[18] which have been remarkably successful in describing the variable emission from 3C120 (ref. 19). In their models a stationary source creates a spherical cloud of relativistic electrons and magnetic field which expands adiabatically. While the source is highly compact, it is optically thick due to synchrotron self-absorption. As the cloud expands, the flux at a given frequency increases until the cloud reaches some critical radius, at which it becomes optically thin at this frequency; thereafter the flux decreases.

Our model differs from earlier models in that we allow the source of particles and/or field to move through an ambient medium of varying density. It is easy to see that apparent superlight velocities can be obtained by this generalisation. Consider the evolutionary sequence in which a source moves out from the centre of a galaxy or quasar with a velocity $v_s < c$. As the energy source moves through the ambient gas it creates a cavity in its wake which is filled with particles and magnetic field. In the regions where the cavity has expanded to a critical radius R_c, corresponding to unit optical depth, the radio surface brightness is at a maximum. This bright region—the apparent position of the radio object—lags behind the actual energy source by a distance $v_s\tau_{exp}$ where τ_{exp} is the time for the cavity to expand to R_c. If the cavity is confined by the ram pressure of an external medium of density ρ, then the expansion velocity is proportional to $\rho^{-1/2}$ and $\tau_{exp} \propto \rho^{1/2}$ (ref. 20). Because the density of the ambient gas decreases away from the centre of the galaxy or quasar, the lag distance decreases as the source moves outward. The apparent position of the radio-emitting region tends to catch up to the energy source. The apparent velocity is thus greater than the actual physical velocity of the energy source. Because this apparent velocity is merely due to a phase-delay effect—the delay of the brightening of the radio object is greater when it is embedded in higher density gas—arbitrarily large velocities could, in principle, be obtained.

A single moving energy source can actually produce two bright emission regions which separate at superlight velocities. If

---

*Present address: Nordita, Blegdamsvej 17, DK-2100 Copenhagen, Denmark.

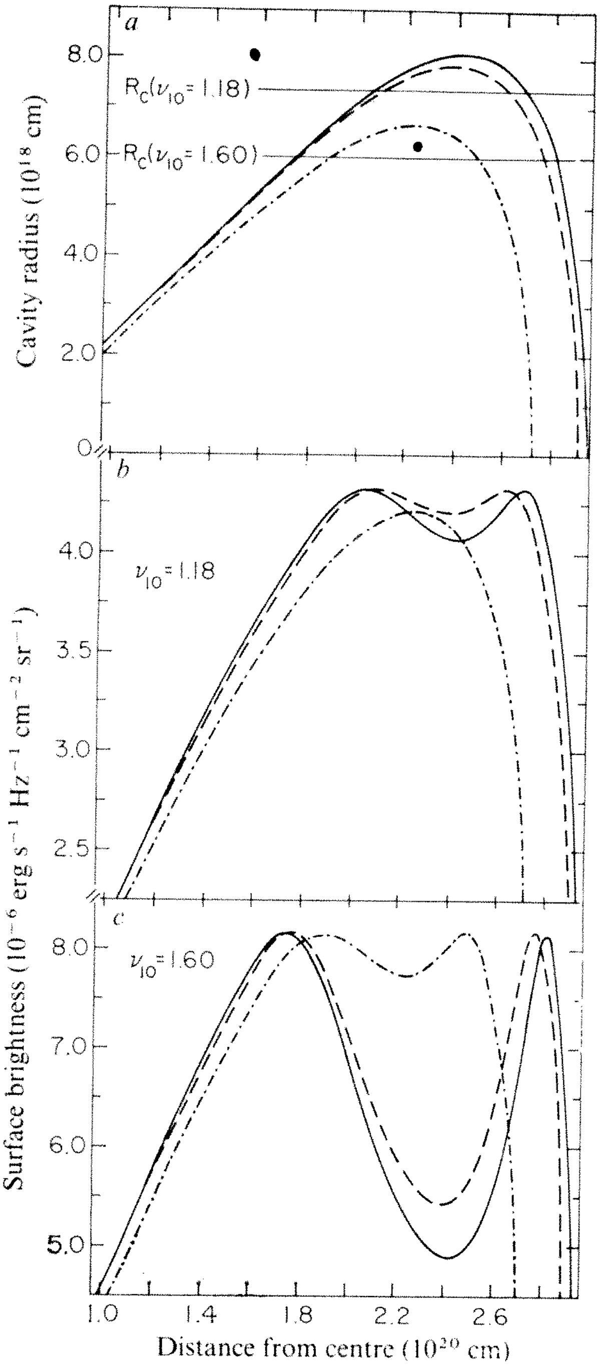

Fig. 1 The evolution of a compact radio object is illustrated at three epochs. *a* The evolution of the cavity boundary. The critical radii for two frequencies are indicated here. *b*, *c* The evolution of the surface brightness along the symmetry axis of the cavity for each of these frequencies. –·–·–, $t = 1.830 \times 10^{10}$ s; – – –, $t = 1.955 \times 10^{10}$ s; ———, $t = 1.980 \times 10^{10}$ s.

the ambient gas is sufficiently concentrated toward the centre of the galaxy or quasar, the cavity expands very slowly in these dense regions and has its maximum diameter somewhere between the centre of the quasar or galaxy and the location of the energy source. This point is illustrated in Fig. 1. Figure 1*a* shows an example of an evolutionary sequence for the cavity radius; the critical radii for two frequencies are indicated. Figure 1*b* and *c* show the corresponding evolution of the brightness distribution.

Consider the cavity to be divided into disk-like segments of fixed thickness along the direction of motion. As each segment expands, the brightness at a given frequency increases until the segment reaches a critical radius; the brightness then decreases as the segment expands further. As long as the radius of the cavity is everywhere less than the critical radius, the brightness distribution exhibits a single maximum which coincides with the position of the maximum cavity radius (cf., brightness distribution for $\nu_{10} = 1.18$ at $t = 1.83 \times 10^{10}$; where ν_{10} is the frequency, units 10^{10} Hz). With further expansion, some portions of the cavity exceed the critical radius. The brightness distribution then becomes bimodal and the regions of greatest brightness occur where the cavity radius is equal to the critical radius.

When the maximum radius of the cavity is only slightly greater than the critical radius, the two brightness maxima separate with arbitrarily large velocity, but the brightness distribution has a very shallow minimum. During the subsequent evolution the apparent separation velocity decreases and the bimodal structure of the brightness distribution becomes more pronounced.

As the energy source moves into regions of lower density, the separation between the leading bright region and the source decreases due to the decreasing τ_{exp}. The leading bright region therefore moves forward faster than the energy source. The trailing object moves towards the centre of the galaxy or quasar with a smaller, but comparable velocity so that the two bright regions separate with an apparent velocity which is significantly greater than the velocity of the energy source and which can easily be superluminal.

This mechanism for producing rapidly separating pairs of bright regions has a well-defined signature which may be deduced from the frequency dependence of the critical radius and the geometrical nature of the model. Since synchrotron-self absorption decreases with frequency[21,22], the critical radius is larger at lower frequencies as indicated in Fig. 1*a*. As can be seen from the figure, a pair of bright regions observed simultaneously at two different frequencies should have the following characteristics: at the lower frequency which corresponds to a larger R_c (1) the two sources are closer together, (2) the brightness minimum between the two sources is less well defined and (3) the individual component radii which are roughly proportional to R_c are larger.

To make more quantitative estimates of the physical structure and brightness distribution of a radio source, one must formulate an explicit and hence more elaborate model. Any such model requires a number of simplifying assumptions about the gas distribution in the centres of galaxies and quasars, about the nature of the energy source and about the mechanisms which operate within the cavity. A model of this sort, though at best heuristic, can serve to illustrate the general interrelationships among the properties of compact objects, galaxies and quasars and extended radio sources.

The model

The gas density in the galaxy or quasar is assumed to be constant near the centre and to decrease at some power law at large distances, z, from the centre according to the relation

$$\rho(z) = \rho_0(1 + z/z_0)^{-n} \tag{1}$$

where ρ_0 is the central density and z_0 is a core radius. The energy source moves away from the centre of the density distribution with a constant velocity v_s and deposits energy at a uniform rate in the form of relativistic particles and field.

It is assumed that each segment of the cavity evolves independently in two dimensions; that is, energy flows along the length of the cavity are assumed to be small compared with the work done by the cavity in expanding in the radial direction. This approximation is reasonable for the model presented here. For the highly elongated cavities, the pressure gradients along the cavity are small in the regions of interest; thus the time scale for energy flow along the cavity should be long compared with the typical radial expansion time.

The rate of expansion of the radius of the cavity at a given distance, z, is determined by the balance of the internal pressure, P_i, and the ram pressure of the external medium, $\rho\dot{r}^2$

$$\dot{r}(z,t) = (P_i/\rho(z))^{1/2} \text{ for } t > z/v_s \tag{2}$$

The internal pressure derives from the magnetic field, assumed to be chaotically oriented, and from the relativistic electrons and heavy particles. The energy densities of the magnetic field and of the relativistic electrons are, respectively, $U_M = B^2/8\pi$ and $U_e = \delta U_M$. The internal pressure is defined as κU_M, where the parameters δ and κ are constants of the energy source. For each slice of the cavity, the evolution of the magnetic field is prescribed by the relations

$$B = B_0 \quad \text{for } 0 < r \leq R_0 \tag{3a}$$

and

$$B = B_0 (r/R_0)^{-4/3} \quad r > R_0 \tag{3b}$$

The first phase (equation (3a)) is the input of energy at a rate

$$W = 3\kappa B_0^2 R_0^2 v_s/4 \tag{4}$$

This rate corresponds to filling the cavity of radius R_0 with particles and magnetic field and to accelerating the ambient gas of the cavity to the velocity given by equation (2). During the second phase (equation (3b)), the cavity expands adiabatically in two dimensions.

To complete the description of the model the energy distribution of the relativistic electrons must be specified. Initially, the distribution is taken to be a power law in energy at high energies

$$N(E)\,dE \propto E^{-m}\,dE \quad E > E_c \tag{5}$$

where $m > 2$. A specific choice of m, E_c and δ defines the proportionality constant in equation (5). We assume that the evolution of the spectrum is entirely determined by adiabatic changes which preserve the power law spectrum and require that $E \propto B^{1/2}$. This implies that other energy loss processes are either inconsequential or are counterbalanced by ongoing electron acceleration. In the case where the source velocity is perpendicular to the line of sight, the intensity of the radiation segment of the cavity of length dz is approximated by

$$I dz = 2r dz \frac{\eta}{\mu} (1 - \exp(-\tfrac{1}{2}\pi r \mu)) \tag{6}$$

where η and μ are the vacuum synchrotron emissivity and opacity, respectively. Expressions for η and μ are taken from refs 21 and 22. The surface brightness is approximately $I/2r$.

The parameters chosen for the model illustrated in Fig. 1 are $v_s = 1.5 \times 10^{10}$ cm s^{-1}, $\rho_0 = 1.72 \times 10^{-8}$ g cm^{-3}, $z_0 = 2.2 \times 10^{19}$ cm, $n = 10$, $B_0 = 3.8$ G, $R_0 = 1.4 \times 10^{18}$ cm, $\delta = 0.01$, $\kappa = 2$, $m = 3$. The parameters are chosen so that the expansion velocity is non-relativistic during the period of interest. The two frequencies $\nu_{10} = 1.18$ and $\nu_{10} = 1.6$ correspond to observing wavelengths of 3.8 and 2.8 cm for a source with a redshift $z = 0.5$.

At the first epoch illustrated in Fig. 1, the source is about 600 yr old, but the double structure, the large apparent separation velocity and high luminosity are just beginning to emerge. The second and third epochs are separated by 8.3 yr, characteristic of an observing interval. Between the second and third epochs, the peaks of the brightness distribution at both frequencies separate with average velocities greater than c. The low frequency brightness peaks are 40% closer together and separate at a velocity about 25% higher than the high frequency brightness peaks.

For the parameters of our model B_c, the field in the region of the cavity where the radius equals R_c, is ~ 0.1 G.

An electron which radiates at about 10^{10} Hz in this field has a radiative lifetime of the order of a few years, which is much shorter than the age of the source. As presently formulated, the model thus requires that some mechanism continually replenish the higher energy electrons. This requirement is not a serious problem for the model. The necessity of some sort of *in situ* acceleration is a feature of many radio source models[15], and the model parameters can be chosen to make the energy in the magnetic field sufficient to compensate for radiation losses for several thousand years.

For $B_c \sim 0.1$ G, the rate of energy input to the cavity (equation (4)) can be estimated as

$$W \sim 2 \times 10^{46}\,\kappa\,(R_c/R_0)^{2/3}\,(v_s/c) \text{ erg s}^{-1} \tag{7}$$

(see equations (3b) and (4)). The total energy which is supplied to a cavity of length Z is WZ/v_s. For a cavity 100 pc long, this energy is of order 10^{57} erg.

The ambient gas density at the point, z_c, where the double source structure first appears can be derived from equation (2). Integration of this equation from time z/v_s to t yields an expression for the cavity radius. Solving for the gas density at the location of the maximum cavity radius gives

$$\rho(z_c) \sim 10^{-22}\,\kappa \left(\frac{B_c H_\rho c}{R_c v_s}\right)^2 \text{ g cm}^{-3}. \tag{8}$$

Here $H_\rho \equiv \rho/(d\rho/dz)$ is the density scale height at z_c. There is approximately a factor of 2 uncertainty in equation (8) due to the choice of R_0/R_c.

In order to achieve large apparent velocities the density scale height has to be of the same order as the separation of the bright regions; H_ρ/R_c is less than about 10. For this sort of density gradient equation (8) yields densities of 10^{-21} to 10^{-18} g cm^{-3}. The central density of the model shown in Fig. 1 is actually much greater than the above estimates; however, this high density is an artefact of the simple density distribution which was used (equation (1)) and does not provide an important physical constraint on the model.

The skewing of the cavity apparent in Fig. 1*a* is directly related to the steep density gradient. The lower gas density near the energy source allows a more rapid radial expansion causing distension towards the source. The positions of the leading bright regions at different frequencies, as determined by the intersections of the cavity boundary with the critical radii in Fig. 1*a*, are thus fairly close together. For steeper density gradients, the positions of these bright regions would be even less frequency dependent.

Discussion

We have shown that a source of relativistic electrons and magnetic field which moves out through the gas in the centre of a galaxy or quasar can produce two bright emission regions which separate at superlight velocities. The energy source must travel at a few tenths the speed of light and must deposit about 10^{57} erg over several tens of pc. Our model is not dependent on the specific nature of the energy source or the detailed mechanism for providing directionality. The source is perhaps a rapidly moving condensed object[23,24] or simply a region where a beam of plasma interacts with the ambient gas[25-27]. The densities and scale heights which are required to yield rapidly separating double radio sources are consistent with the estimates of the properties of galactic nuclei and quasars which are deduced from optical studies[28].

The basic phenomenon described here has several distinctive characteristics which are essentially model independent: the bright regions should be smaller, more separated and have deeper minima between them when observed at higher frequencies. Furthermore, the pair of bright regions should not be symmetric with respect to the centre of the optical brightness distribution of the galaxy or quasar.

Within the context of the specific model formulated here, the structure of the bright regions is sensitive to the gas density scale-height; the structure is less frequency dependent when the density gradient is steeper. In active galactic nuclei or quasars the required steep density gradients would develop as a result of violent events. Some of the assumptions which were made to develop the simple model shown in Fig. 1 should be relaxed to correspond more closely to the actual physical reality. One might, for example, expect to find irregularities in the density distribution, in the rate at which the source supplies energy, or in the source velocity. These may lead to fluctuations in the brightness of the components and in variations in the apparent velocity of separation. In addition, the source velocity need not be perpendicular to the line of sight. Interesting relativistic effects occur when a bright region moves at a high or superluminal velocity at small angles with respect to the line of sight[11,12,29]. The apparent separation velocities of the bright components can be enhanced, and a single bright region moving toward the the observer may appear as two rapidly separating components.

The expansion velocity of the source itself may be relativistic. Existing models which employ relativistic expansion to explain rapid variability in radio sources would imply extremely high velocities in some exceptional cases[9]. This rapid variability is more easily explained in terms of a highly extended cavity which expands relativistically: because the cavity can be elongated by a factor of 20 or more when maximum brightness is attained, the surface over which coherent expansion occurs is greatly increased. It should be noted that rapid variations observed at one frequency may indicate that at higher frequencies the source may appear as two rapidly separating components.

We are grateful to Bill Cotton, Irwin Shapiro, and Jill Wittels for their encouraging discussions and critical assessments of the current observations. George Rybicki pointed out a number of interesting relativistic effects. We also enjoyed discussions with Al Cameron, Marc Davis, Dave DeYoung, George Field, Bill Saslaw and Greg Shields. One of us (R.I.E.) wishes to acknowledge the hospitality of the Aspen Center for Physics where some of this work was done. This work was supported in part by a grant from the USNSF.

A simple physical model for X-ray burst sources

THE observational properties of X-ray burst sources have recently been reviewed by Grindlay[1] and Lewin[2]. These sources are concentrated in the direction of the galactic bulge and near the galactic plane. If they are at a mean distance of ~ 10 kpc and the burst radiation is emitted isotropically, then the time-averaged luminosities in bursts are typically ~ 10^{34}–10^{36} erg s^{-1}. Several of these sources may also have relatively steady X-ray luminosities[2]. Because of the limited sky coverage of available X-ray astronomy satellites, it seems likely that there are many times more burst sources in the galaxy than have heretofore been discovered.

There are ~ 150 known "steady" galactic X-ray sources[3], which are also concentrated toward the galactic bulge and in the galactic plane and have luminosities of up to ~ 2×10^{38} erg s^{-1}. The most widely accepted model for many of these sources consists of a compact object that is accreting matter from a close binary stellar companion[4]. For many of the galactic-plane sources with identified optical counterparts, the companion stars are OB supergiants, and there is some evidence that these stars nearly fill their critical potential lobes (see, for example, refs 5 and 6). The wind emitted by the companion star may well be enhanced by its proximity to its critical lobe[6,7]. Although the evolutionary time scale of an OB star fromthe main sequence to the supergiant stage is about 10^6–10^7 yr, it has been argued on statistical and theoretical grounds that a binary system containing such a star and a compact object becomes a bright X-ray source for only ~ 10^4–10^5 yr preceding the filling of the critical lobe of the OB star (ref. 7; ref. 8 and references therein).

The above information suggests a simple physical model for an X-ray burst source in the galactic disk, comprised of an unevolved OB star with a relatively weak stellar wind and a compact object in a close binary system. For some (as yet undetermined) reason, the stellar wind from the OB star is unable to accrete steadily on to the compact object unless the accretion rate, and hence the average X-ray luminosity, exceeds some critical value. Thus, when the stellar wind is sufficiently weak, the compact object accretes irregularly, leading to X-ray bursts. If this picture is correct, then many present burst sources will evolve into bright "steady" X-ray sources when the associated OB stars evolve and approach their critical lobes.

Accretion by a compact object from the weak stellar wind of a companion is also a tenable model for the burst sources associated with the galactic bulge. However, the stellar population of the galactic bulge is probably very different from the disk population, and the evolutionary histories and other detailed properties of the bulge burst sources are thus likely to be different from those of the disk burst sources. (The apparent association of three burst sources with globular clusters (refs 1 and 2 and references therein) strongly supports the identification of a subset of these sources with Population II objects.)

A magnetised neutron star is the most plausible candidate for the compact object in an X-ray burst system[9]. Theoretical studies have indicated that the character of spherical accretion on to a magnetised non-rotating neutron star changes[10], and that steady accretion might in fact not occur (F. K. Lamb, A. C. Fabian, J. E. Pringle, and D. Q. Lamb, submitted to *Astrophys. J.*), if the time-averaged X-ray luminosity $\lesssim 10^{36}$ erg s^{-1}. The rotation period of the neutron star may also play a critical role in determining the steadiness of the flow[9].

For rotating neutron stars with sufficiently low luminosities or sufficiently short rotation periods, the corotation velocity in the vicinity of the Alfvén surface will be larger than the circular Keplerian orbital velocity. This results in an effective centrifugal barrier[9-11] that should inhibit the steady accretion of matter and provide a mechanism for the storage of matter above the neutron-star surface (ref. 9; ref. 12 and references therein). For a $\sim 1\ M_\odot$ neutron star of radius $\sim 10^6$ cm, corotation at the Alfvén surface is determined by the following approximate relation (see refs 11, 13) between the rotation period, P, the time-averaged luminosity, L, and the neutron-star magnetic moment, μ

$$P \sim 0.2\left(\frac{L}{10^{37}\ \mathrm{erg\ s^{-1}}}\right)^{-3/7}\left(\frac{\mu}{10^{30}\ \mathrm{G\ cm^{3}}}\right)^{6/7}\ \mathrm{s} \qquad (1)$$

For more rapid rotation, matter is likely to accumulate and compress the Alfvén surface until accretion on to the neutron-star surface can proceed. Under these evidently unstable conditions, bursting behaviour may result.

The observed values of X-ray luminosity and rotation period for the nine known binary X-ray pulsars are shown in Fig. 1. It is likely that these objects are all rotating magnetised neutron stars undergoing accretion of mass from binary stellar companions (ref. 14 and references therein). The relation $P \propto L^{-3/7}$ is superimposed on the figure and normalised so as to pass through the parameter values of Hercules X-1, which seems to be in a near balance between spinup and spindown (ref. 12 and references therein). Most of the X-ray pulsars lie substantially above this line; the 'missing' neutron stars that lie below this line may be X-ray burst sources.

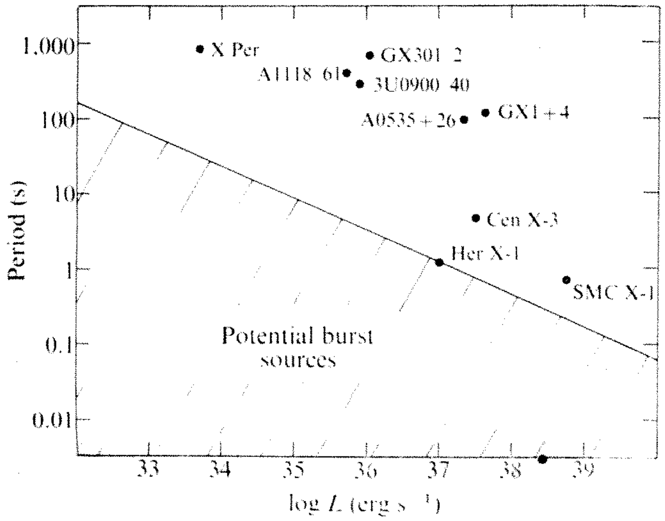

Fig. 1 Observed values of typical X-ray luminosity, L, and pulse period, P, for nine X-ray pulsars (see ref. 19). (For the transient sources A1118–61 and A0535+26, the maximum observed luminosity is indicated. The indicated pulse periods and luminosities are taken from ref. 20 and references cited therein. The straight line with logarithmic slope of −3/7 represents the relation between X-ray luminosity and pulse period such that matter in a circular Keplerian orbit will corotate with the neutron star at the Alfvén surface[11,13,19]. The line is normalised so as to pass through the parameter values of Hercules X-1 (see text). For neutron stars which lie below this line, matter that reaches the Alfvén surface cannot corotate because its rotational velocity would then exceed the circular Keplerian orbital velocity, and such matter may therefore be unable to accrete steadily across the surface[9,11].

We note that X-ray bursts have been observed from the direction of the bright 'steady' sources Serpens X-1 (3U1837+04), A1905+00, MX1728−33, and 3U1820−30, to within positional accuracies of $\sim 0.1°$ (ref. 2 and references therein). Other burst sources may also have substantial 'steady' luminosities (refs 1, 2, and references therein). If the observational identification of bursts with bright 'steady' sources is confirmed, then the presence of bursting behaviour in a binary stellar system containing a compact object must depend upon additional parameters besides the time-averaged luminosity. For example, if the burst sources are rotating neutron stars, then the neutron-star rotation period and magnetic moment presumably also have a role in determining the existence of bursting behaviour[9] (see equation (1)).

If our suggested identification of burst sources with binary systems containing compact objects is correct, then several predictions are possible. First, as more burst sources are discovered, the spatial distribution of the burst sources should follow the distribution of the 'steady' galactic sources (although the ratio of galactic-bulge objects to disk objects may be different for the burst sources than for the 'steady' sources). Second, the ratio of the total number of disk burst sources to "steady" disk sources should be comparable to the ratio of the main-sequence lifetime of an OB star to its lifetime in a state of enhanced stellar wind as it approaches its critical potential lobe (that is, $\sim 10^1$–10^3). Third, for some sources with slowly varying 'steady' X-ray luminosities, one should see transitions between bursting behaviour when the time-averaged luminosity is low and no bursts when the luminosity is high. This phenomenon has already been observed in the source 3U1820–30 (ref. 15). Other examples of this type of effect might be the onset of bursting behaviour during the extended inactive states of transient sources and Hercules X-1-type systems. Fourth, the existence of very large bursts from relatively nearby binary systems ($\lesssim 1$ kpc) is predicted. For some of these sources, it may be relatively easy to identify the optical companion star. It has previously been suggested[16,17] that the high-energy tail of nearby X-ray bursts could account for the observed γ-ray burst events[18]. However, we note that the repetitive nature of the bursts from many of the X-ray burst sources is apparently not characteristic of the γ-ray sources.

We are grateful to W. Baan, J. Bahcall, D. Lamb, F. Lamb, W. Lewin and P. Morrison for discussions. This work was supported in part by the National Aeronautics and Space Administration. Both of us also acknowledge support from the Alfred P. Sloan Foundation.

Detection of change in rotation measure of the Vela pulsar

OBSERVATIONS made over the past six years show that the rotation measure of the Vela pulsar has increased by 14%, while over the same period the dispersion measure has shown a marginally significant decrease of about 0.2%. These results imply that a region containing a relatively strong magnetic field has moved across the path to the pulsar. This region of strong field is most probably associated with filamentary structure in the Vela supernova remnant.

Using a polarimeter giving simultaneous measurements of all four Stokes parameters[1] we obtained observations of PSR 0833−45 at well separated frequencies on three occasions, December 1971, July 1975 and June 1976, as shown in Table 1. Except for the 338 MHz measurements, data were obtained at several frequencies within the bands given in Table 1, the measurements being simultaneous at either two or three frequencies within a band. Observations in different bands were separated by a few days for the 1971 and 1976 observations and by 3 weeks for the 1975 observations. These observations permitted accurate determinations of the rotation measure along the path to the source and of the position angle of the emitted radiation extrapolated to infinite frequency, the intrinsic position angle. The results of these measurements are given in the table and are plotted in Fig. 1 together with data from Komesaroff *et al.*[2,3], who observed the source in May 1970 at a number of frequencies simultaneously using a single linearly polarised feed at each frequency. The rotation measure of the Vela pulsar was determined at earlier epochs by Radhakrishnan and Cooke[4] and Ekers *et al.*[5], but their data are less precise than the more recent measurements and so are not included in Table 1. All rotation measures have been corrected for the effects of Faraday rotation in the Earth's ionosphere using concurrent measurements of the critical reflection frequency f_0F2. The correction was in the range of 0.7 – 1.3 rad m^{-2} for these observations and is estimated to be uncertain by less than 10%.

It is clear from Fig. 1 that there has been a significant change in the rotation measure along the path to the source during the past 6 yr. The fact that there has been no significant change in the intrinsic position angle confirms that the observed changes result from variations in the rotation measure rather than in the emitted position angles. It also provides an *a posteriori* justification for the assumption of a ν^{-2} position angle dependence between the different frequency bands.

For the 1975 and 1976 observations, dispersion measures were also computed from the 631–649 MHz data; the results are shown in Table 1 and Fig. 1. There is some indication that the dispersion measure has decreased between 1970 and 1976.

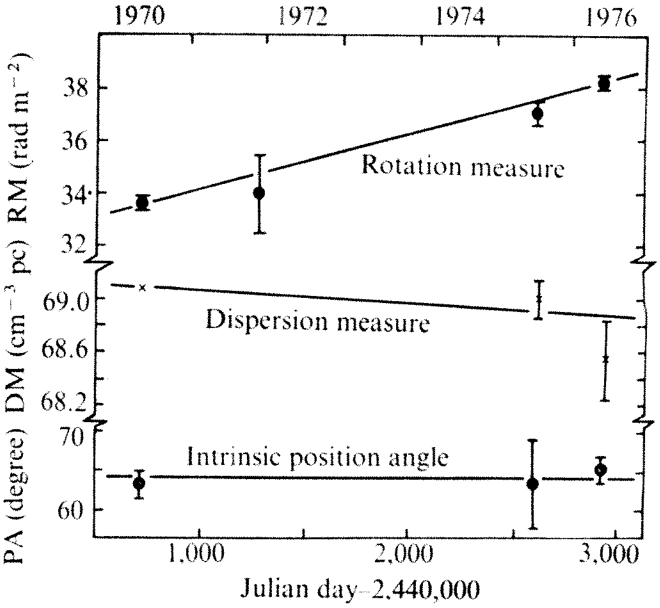

Fig. 1 Rotation measure, dispersion measure and intrinsic position angle of PSR 0833−45 at different epochs. For the rotation and dispersion measures the lines represent least-squares fits to the data, whereas for the intrinsic position angle the line has zero slope.

For the rotation and dispersion measure data, the straight lines in Fig. 1 represent weighted least-squares fits to the observations and have slopes of 0.77±0.04 rad m^{-2} yr^{-1} and 0.033±0.030 cm^{-3} pc yr^{-1} respectively (1σ errors). If the dispersion measure change is real and associated with the rotation measure change, then the implication is that a region of excess electron density has moved out of the path to the pulsar during the past 6 yr. Since the rotation measure increased during this time, the mean line-of-sight component of the magnetic field in this region must have been directed toward the pulsar giving a negative rotation measure contribution. This is in the opposite sense to the mean interstellar field in this direction.

The short timescale of the changes suggests that the region concerned must be relatively small. One possibility is that the changes occurred within the pulsar magnetosphere itself. There is, however, good evidence that little or no Faraday rotation occurs within this region[6]. We therefore assume that the changes are taking place within the interstellar medium. The scale of the region may be estimated from the relative velocity of the pulsar and the medium. It is likely that the highest relevant velocity is that of the pulsar; observations of pulsar proper motions[7,8] show that pulsars typically have velocities in excess of 100 km s^{-1}. The offset between the position of PSR 0833−45 and the centre of symmetry of the Vela supernova remnant together with the pulsar characteristic

Table 1 Rotation measure, dispersion measure and intrinsic position angle for PSR 0833−45

Date	Observing frequencies (MHz)	Rotation measure (rad m^{-2})	Dispersion measure (cm^{-3} pc)	Intrinsic position angle (°)	Reference
May 1970	300, 410, 467 628, 1410	33.6±0.1	69.08±0.01	63.1±1.5	2, 3
December 1971	338, 395–400	33.9±1.5	—	—	Present work
July 1975	631–649, 1612–1720	37.0±0.17	68.99±0.13	63.5±5.7	Present work
June 1976	268–278, 631–648	38.17±0.06	68.53±0.3	65.2±1.5	Present work

age suggests that the Vela pulsar may have a transverse velocity as large as 500 km s^{-1}. If we adopt this figure as a reasonable upper limit to the velocity, an interval of 6 yr corresponds to a transverse scale length of 3×10^{-3} pc or 600 AU for the electron density and field fluctuation. If we further assume that the line-of-sight dimension of the region is comparable, then the excess electron density corresponding to a dispersion measure change of ~ 0.20 cm^{-3} pc is about 65 cm^{-3}. Of course, if the region has smaller dimensions the electron density would be greater.

Since this electron density is high relative to normal interstellar values we can approximate the weighted mean line-of-sight component of the magnetic field in the time-varying region by

$$\langle B_1 \rangle = 1.23\, \Delta(\mathrm{RM})/\Delta(\mathrm{DM})$$

where Δ(RM) and Δ(DM) are in their conventional units and $\langle B_1 \rangle$ is in microgauss. For $\Delta(\mathrm{RM}) \sim 4.5$ rad m^{-2} and $\Delta(\mathrm{DM}) \sim 0.2$ cm^{-3} pc we have $\langle B_1 \rangle \sim 30$ μG. This estimate will be too high if the electron density in the region concerned is larger than that assumed, either because of an underestimate of the dispersion measure change or because of the presence of a non-varying component. The estimate will be low if the dispersion measure change is less than that assumed.

It is well known that supernova remnants contain filaments of enhanced optical and non-thermal radio emission. The small indicated size of the time-varying region, together with the relatively strong magnetic field and high electron density values derived above, suggests that the observed changes result from the motion of a filament in front of the pulsar. The derived parameters are well within the range of those found for filaments in supernova remnants. For example, Duin and van der Laan[9] deduce that filaments in IC 443 have typical dimensions of 10^{-3} to 10^{-2} pc, magnetic field strengths of 150 μG and electron densities of 250 cm^{-3}. Bell *et al.*[10] deduce even larger field strengths for regions of intense radio emission in Cassiopeia A, about 3,000 μG. An Hα survey of the Vela supernova remnant by Elliott *et al.*[11] showed no evidence for an intense filament in the vicinity of the pulsar. However, diffuse nebulosity was detected in this region. The present results suggest that this nebulosity contains small-scale structure and regions of enhanced magnetic field.

Observational consequences of synchrotron self-Compton models of compact extragalactic X-ray sources

RECENT measurements[1-6] have confirmed the existence of a class of extragalactic X-ray sources quite different from those associated with clusters of galaxies. These sources (Cen A, NGC4151, NGC1275, 3C390.3 and 3C273) are characterised by flat X-ray spectra, low-energy X-ray absorption, strong optical emission-line spectra and a compact radio or millimetre component[4]. These observations give strong impetus to the construction of models[7,8] in which these phenomena are related. We report here some of the results of a synchrotron self-Compton model[9] (SSC) which we feel can account for many of these observational properties. This model includes the effects of adiabatic expansion and synchrotron losses. We concentrate here on two of the three most studied sources—NGC4151 and NGC1275—and report our results on Cen A elsewhere. We use the results of this analysis to make tentative observational predictions about the colours of the nuclei of potential X-ray sources.

In this SSC model the non-thermal radio, X-ray, and optical emission originate in an extremely small region located in the nucleus of the galaxy. The non-thermal flux causes photoionisation of the gas in this nucleus which results in the observed strong emission-line optical spectrum. In addition this gas absorbs low-energy X-rays causing a turnover in the X-ray spectrum.

We can determine several physical properties of this emitting region, assuming X-ray emission due to SSC radiation, that is, that X rays are produced by the Compton scattering of lower energy synchrotron photons off the radiating population of relativistic electrons. Two relations between observables are[7]:

$$B \approx 7.42 \times 10^{-60}\, i_{ao}^{2}\, \nu_n^{5}\, \theta_s^{4}\, F_{\nu_n}^{-2} \text{ gauss} \qquad (1)$$

and

$$F_{\nu_x} \approx F^2_{\nu_n} (\nu_x/\nu_n)^{-\alpha}\, \nu_n^{\alpha}\, \theta_s^{-2}\, B^{-(1+\alpha)} \qquad (2)$$

$$[2.75 \times 10^4\, e_{ao} (2.79 \times 10^6)^{-(1+\alpha)} \ln \Lambda]\ \text{erg cm}^{-2}\ \text{s Hz}$$

where F_{ν_x} is the X-ray flux at the frequency ν_x, θ_s is the angular size of the source (radians), B is the magnetic field in the emitting region, F_{ν_n} is the radio or millimetre flux at the synchrotron self-absorption frequency ν_n, and i_{ao}, e_{ao} and ln Λ are functions of order unity discussed by Jones *et al.*[7]. We have assumed isotropic disordered magnetic fields and no reisotropisation of pitch angles.

Assuming that the hard $E^{-0.4}$ energy X-ray spectrum of NGC 4151[1,10], which exists out to at least 100 kev, originates by the SSC process in a component for which ν_n is in the millimetre band, as is required by recent upper limits (M. Werner 1976, H. Hudson and T. Soifer 1975, personal communications), we determine that $\theta \approx 1.4 \times 10^{-5}$ arc s (~ 1.5 light d at 19 Mpc (ref. 11)), $B \approx 2$ G, and that the synchrotron lifetimes of electrons responsible for the 2–10 keV X rays is ≈ 7 d. Here we neglect any effects due to adiabatic expansion. The model predicts that a sudden injection of a large number of relativistic particles would result in an X-ray flare for which the rise and decay times would each be a few days. The time scale of flux increase is that of the filling of the emission region by relativistic particles; the time scale of decay is that of synchrotron energy losses. We expect the X-ray spectrum to steepen with both time and energy during the decay period, so that the length of an observable flare should be shorter at higher X-ray energies. The X-ray spectral index should be

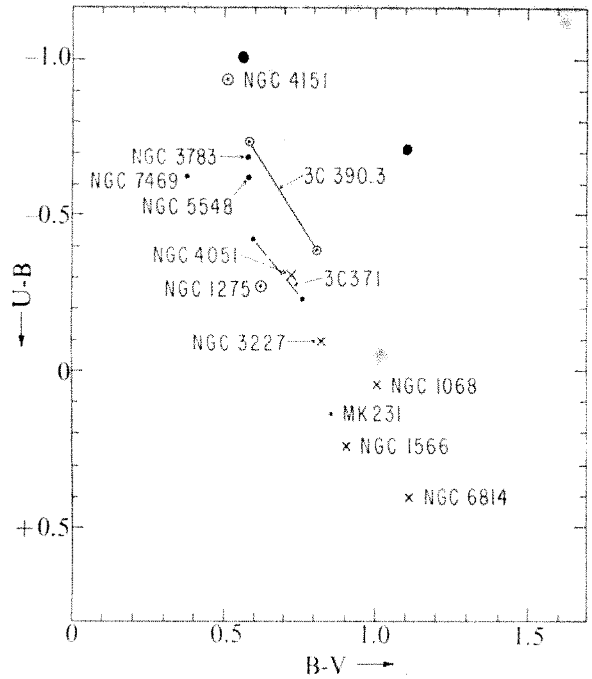

Fig. 1 The colour–colour plot for the nuclei of selected active galaxies. The lines represent the various colours seen in the nuclei of 3C390.3 and 3C371. The crosses mark those sources shown not to have detectable X-ray emission, the circles those known at this time to emit X-rays, and the dots are objects unobserved in the X-ray. The relative contribution of non-thermal radiation to the optical flux of a galactic nucleus increases from lower right to upper left in the U–B, B–V plane.

about the same as the radio (millimetre) index up to a high frequency radio break. Above this break frequency, the source should produce a power law infrared (IR) and optical flux with index $\alpha_{IR} \approx (4\alpha_{X\text{-ray}} + 3)/3$, where $\alpha_{X\text{-ray}} = \alpha_{mm}$ is the X-ray energy index. Since $\alpha_{X\text{-ray}} \approx 0.39$ (Ives *et al.*[2]) we expect $\alpha_{IR} \approx 1.52$, which is close to our $\alpha_{IR} \approx 1.46$ power law fit to the 2.2–21 μm data of Rieke and Low[12].

This model predicts a detectable flux of ~ 10 Jy at 300 μm from NGC 4151, that there should be no correlation between the MHz radio and X-ray flux, and that the X-ray absorption should be due to material in the forbidden line and broad-emission-line regions of the optical nucleus (ref. 2 and G. Shields and R.M., unpublished).

A similar model can be developed for NGC 1275 using the recent radio data of Pauliny-Toth *et al.*[13]. Here observations give $\nu_n \sim 8.5$ GHz, $F_{\nu_n} \sim 71$ Jy and $\alpha_{radio} \sim 0.45$ if we assume a single, extremely compact component. To explain the measured X-ray flux from the core of the Perseus cluster[19], presumed to be due to the nucleus of NGC 1275, we derive $\theta_s \sim 1.4 \times 10^{-3}$ s (2.1 light years at 100 Mpc), $B \sim 0.1$ gauss, synchrotron lifetimes of ≈ 10 y and $\alpha_{X\text{-ray}} \approx 0.45$. The measured VLBI[13] angular size is $\approx 1.3 \times 10^{-3}$ s and Burbridge *et al.*[14] find a typical time for variability in the compact radio component of 12 yr. We expect a non-thermal IR and optical flux with spectral index $\alpha_{IR} \sim 1.6$ which agrees well with a power law fit to the aperture-corrected data of Penston *et al.*[15], for which $\alpha \approx 1.56$. It is also expected that NGC1275 should show absorption in its X-ray spectrum and that there will be a correlation between X-ray emission and the intensity and turnover frequency of the GHz radio emission.

In this SSC model the non-thermal optical and infrared flux in the nuclei of these objects is related to the X-ray flux. Thus there should exist a correlation between the relative strength of the non-thermal component in the nucleus of a galaxy and the probability of X-ray emission from it. Sandage[16] has shown a relationship between the position of a nucleus in the U–B, B–V plane and the strength of the non-thermal component. In Fig. 1 we show the colour–colour diagram for a sample of well studied low redshift active galaxies. Following Sandage, the colours of the nuclei[16–18] of these galaxies have not been corrected for reddening. We note that all those known as of June 1976 to have X-ray emission (NGC4151, NGC1275, 3C390.3) lie in the part of the diagram corresponding to strong non-thermal components while those objects known not to emit X rays[19] (NGC1068, NGC1566, NGC3227, NGC4051 and NGC6814) lie in a region corresponding to weak non-thermal components. Based on this correlation we suggest that a search be made for X-ray emission from NGC3783, NGC5548, NGC7469 and 3C371.

Absolute scale of thermoelectricity

I HAVE obtained the absolute thermoelectric power of lead between 10 and 350 K by direct measurement of the Thomson heat for the first time. Above 20 K the values are higher than the present scale by up to 0.30 μV K⁻¹. Acceptance of the new values would require the recalculation of the thermopowers of almost all metals, since lead was almost certainly the reference material for the thermocouple measurements which were used to determine them. The size of the correction makes it particularly significant for the theoretical interpretation of the thermopowers of many metals and alloys.

The presently accepted scale of the thermopower of lead is that of Christian, Jan, Pearson and Templeton[1]. They calculated the thermopower S from the voltage V of a lead against superconductor thermocouple and from the Thomson heat μ of lead of Borelius and coworkers (ref. 2 and many earlier papers), as

$$S(T) = \int_0^{T_1} \frac{d^2V}{dT^2} dT + \int_{T_1}^{T} \frac{\mu}{T} dT \quad (1)$$

where T_1 was about 17 K. In fact the Borelius values for μ were obtained indirectly from measurements of the Thomson heat of an alloy and the thermopower of lead relative to the same alloy. The Borelius measurements were made more than 40 years ago and have never been tested below 100 K by comparison with direct measurements of the Thomson heat.

In the present work two identical lead wires were placed in a small temperature gradient ΔT and a direct current i was passed through them (going up the gradient in one wire, down it in the other). The change in temperature δT at the midpoint of one wire on reversal of the current direction was measured by means of a differential thermocouple. (By symmetry, δT is half the change of the temperature of the midpoint of one wire with respect to the temperature of the midpoint of the other wire.) From the general solution given by Nettleton[3] for the temperature distribution in the wire, it can be shown that the Thomson heat can be calculated from

$$\mu = 4kA\,\delta T/iL\,\Delta T \qquad (2)$$

where k is the thermal conductivity; A, the cross-sectional area; and L, the length of each wire. A full description of the experiment will be published later.

The present values of μ/T agree within 5% with the superconducting experiment[1] from 10 to 17 K. The values are several times larger than the earlier values from 20 to 40 K, reconverge at 80 K, and stay within 10% of the earlier values to 290 K.

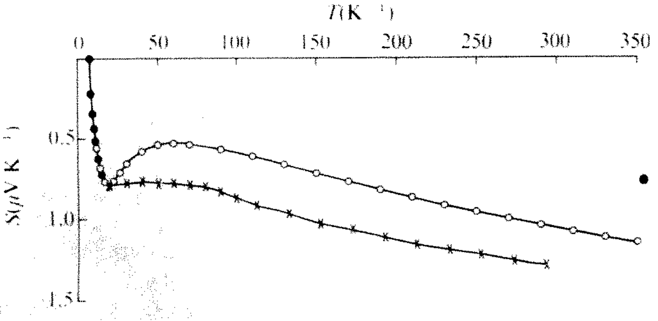

Fig. 1 Absolute thermopower of lead. , Present result; ●, Christian *et al.*[1] thermocouple experiment; , Christian *et al.*[1] compilation of Borelius[2] measurements.

The small region of mismatch of μ/T has a large effect on the thermopower scale. In Fig. 1 the present results have been tied to the old scale at 17 K. The agreement in the overlapping region from 10 to 17 K is within 0.02 μVK⁻¹. Above 17 K the two scales diverge rapidly to be 0.24 μVK⁻¹ apart at 50 K. This difference is approximately maintained at higher temperatures. The new curve is much smoother than the old, and it resembles the thermopower curves of other pure metals, having a well defined phonon drag peak. The thermopower of lead and the difference ΔS between present work and that of Christian *et al.*[1] are given in Table 1. Linear interpolation into ΔS can be used to transform thermopowers on the old scale to the new scale within 0.01 μV K⁻¹.

The measurements on lead were confirmed by the following experiments. The thermopower of a silver–1.2% gold alloy was calculated from 15 to 290 K from measurements on a lead-alloy thermocouple using the new curve for lead. The Thomson heat of the alloy was also measured directly from 15 to 290 K and its thermopower calculated by integrating equation (1) upwards from the thermocouple result at 17 K. The thermopowers agreed within 0.02 μV K⁻¹ over the whole range (see Fig. 2). This test is particularly sensitive to the effect of systematic errors in the Thomson heat measurements because, at most temperatures, the Thomson heat of the alloy is of opposite sign to that of the lead. Any significant heat loss from the sample (the most probable source of error) will cause the magnitude of the observed μ to be too small in each case. The errors are therefore additive. Only if both samples lose no heat will the thermopowers calculated from the Thomson heat results agree with those observed in the thermocouple experiment. These experiments confirm that the new scale is correct within 0.02 μV K⁻¹.

Table 1 Preliminary values of the thermopower of lead and correction to scale of Christian *et al*[1].

T (K)	S (μV K⁻¹)	ΔS (μV K⁻¹)
17	−0.78	0.00
20	−0.78	0.00
25	−0.72	0.06
30	−0.66	0.12
40	−0.58	0.19
50	−0.54	0.24
60	−0.53	0.25
80	−0.54	0.25
100	−0.58	0.28
150	−0.71	0.30
200	−0.83	0.29
250	−0.95	0.26
300	−1.05	—
350	−1.14	—

$\Delta S = S_{Pb}^{Roberts} - S_{Pb}^{Christian}$. A more closely spaced table will be published later.

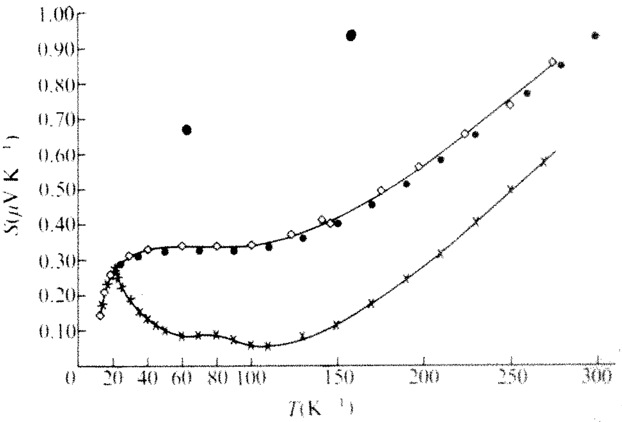

Fig. 2 Absolute thermopower of silver–1.2% gold alloy. ●, From direct measurement of Thomson heat; ◇, thermocouple experiment: Roberts scale for S_{Pb}; ×, thermocouple experiment: Christian *et al.* for S_{Pb}.

Figure 2 also serves as an example of how correcting thermopowers by means of Table 1 can be expected to produce drastic changes in the thermopowers of some alloys. On the Christian *et al.* scale the phonon drag peak for the silver–gold alloy is very narrow. On the new scale it appears very broad indeed, possibly decaying as T^{-1} to room temperature.

Fission/α analysis of the U, Th families

A MODIFICATION is presented here of the technique of particle track analysis (PTA) by means of which it is possible to measure in particular geologic materials not only uranium but also thorium and/or radioactive disequilibria in the U and Th families.

PTA based on slow-neutron-induced fission is by now a standard method for U analysis (ref. 1, and references therein), but the technique has not been so successful for Th. Methods have been proposed based on the fission of Th by various energetic particles[2–5], but few actual analytic studies have been carried out on geologic materials, probably because of the difficulties associated with providing fluxes of such energetic particles which are both sufficiently large and known with sufficient accuracy.

The method proposed here is based both on the slow-neutron fission of U and on the natural α-decay of U, Th, and their radioactive daughters. Cellulose nitrate (CLN) records α-tracks, as other plastics such as Lexan record fission tracks[6]. If a flat surface of a U, Th-bearing material is placed against a sheet of

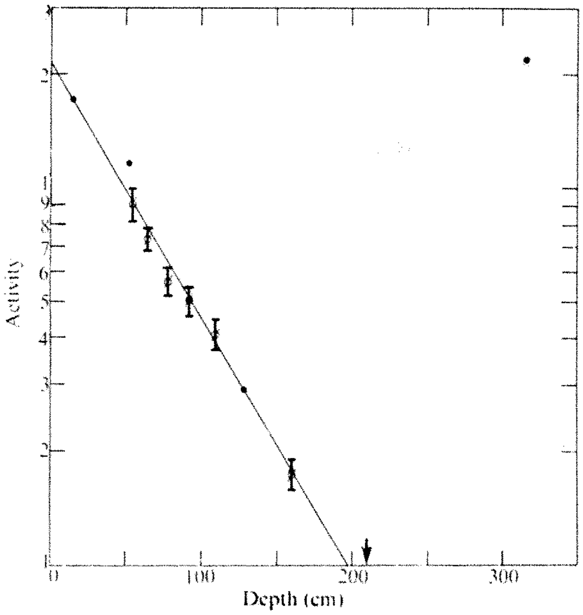
CLN, naturally-occurring α-particles from the U and Th families will impinge on the CLN and leave detectable tracks. The total α-activity of the sample is thus measured. The sample (a disk of pressed powder) is then placed in contact with a sheet of Lexan and irradiated by slow neutrons, for normal fission track analysis of the U alone.

The density of α-particle tracks in the CLN is given by $\rho = Rt$, where R is the rate at which α-tracks are produced per minute per cm² and t is the time the sample is in contact with the CLN. R is given by

$$R = W^{1/2}(k_u U + k_{th} Th) \qquad (1)$$

with W the atomic weight calculated on the atomic fraction basis; k_u and k_{th} constants depending on the decay constants, α-ranges, and counting criteria; and U and Th indicating concentrations in p.p.m. This expression based on the empirical Bragg–Kleeman relation, was first published by Cherry[7], who used it to describe the total α-particle activity measured by thick-sample scintillation counting techniques. I have determined the k-values for the present work by measuring the density of tracks produced in CLN exposed to materials of widely-differing W: U metal foil, ThO$_2$ powder, and artificial glasses with known contents of U and Th[5,8]. These values will vary depending on the individual investigator's criteria for identifying tracks in the CLN; my values are $k_u = 5.15 \times 10^{-4}$, $k_{th} = 1.6 \times 10^{-4}$.

Fig. 1 α-Activity in core V19-61. ●, Excess ^{230}Th activity in d.p.m. g^{-1} (ref. 9). ○, R values, normalised at 93 cm depth.



With the U content of the sample given by the fission track analysis, the Th content can be calculated from equation (1). Table 1 shows the results of some determinations on a variety of geological materials of known U and Th contents.

The time t necessary for the accumulation of α-tracks is a function of the U, Th contents and the accuracy desired. Densities of 100 tracks cm^{-2} are easily measured, but one will normally desire at least several hundred tracks for statistical considerations. Samples with $U = 1$ p.p.m. and $Th/U = 4$ will generate densities of 500 tracks cm^{-2} in about two months. The uncertainty in the determination of Th in these conditions is about 8%.

This method of Th analysis is valid only for those samples in which the U and Th families are in radioactive equilibrium, since it is the total α-activity of the sample that is measured. This is an important but not too severe a geologic restriction. Perhaps even more important are certain types of sample which do not meet the conditions of radioactive equilibrium. Those samples which have lost or gained any of the radioactive daughters gradually or non-quantitatively, by such processes as weathering or migration, must simply be discarded, but there are certain geological processes which establish radioactive disequilibria in precise conditions, and these may be investigated by this technique.

One particular example is the deposition of deep-sea sediments, in which an excess of ^{230}Th over that established by radioactive decay from ^{238}U is deposited, owing to the much lesser solubility of Th than U in water. As the sediment is buried by succeeding debris, this ^{230}Th (being unsupported by any longer-lived parent) decays away with its characteristic half life of 7.5×10^4 yr until equilibrium is established at a lower activity level by the U present. The decay of excess ^{230}Th is one means of establishing deep-sea sedimentation rates[9]. Other nuclides in the U and Th families may also be deposited out of equilibrium, but previous studies have shown that ^{230}Th is much the dominant species.

Measurements of the total α-activity in such sediments, corrected for α-activity in equilibrium with the U present, should show this characteristic decline with depth unless significant postdepositional mobility of members of the U, Th families should separate the various components of the total α-activity and thus disturb the correlation. Figure 1 shows the results of such an investigation into core V19-61 collected by the Lamont Observatory from near the East Pacific Rise, for which an excess ^{230}Th chronology has been established[9]. The straight line is the best fit through the ^{230}Th points: clearly the total α-activity data show the same slope, and therefore the same sedimentation rate as that obtained by direct measurement of the ^{230}Th.

The advantage of the fission/α-particle (f/α) technique is its simplicity and rapidity. Although experimental data on deep-sea sedimentation rates are of extreme value, there are very few such data in the literature because of the laborious procedures involved in the wet chemistry and α-spectrometry necessary for ^{230}Th measurements. On the other hand, all the f/α data of Fig. 1 represent one day's work. General applicability of the f/α method to this problem will depend on the question of postdepositional mobility of the U. Th families in deep-sea sediments; the lack of such mobility observed in core V19-61 may not be a common feature of ocean basins. The ease of the method will greatly facilitate the necessary surveying studies.

Many similar geological situations exist, in which the f/α method may be useful. Sediments with very high rates of sedimentation may be analysed by measuring the growth of the ^{226}Ra daughter of the excess ^{230}Th (half life 1622 yr) for the first few thousand years and then the decay of the ^{230}Th and its daughters after the Th–Ra equilibrium has been established. Corals incorporate U preferentially to Th, and so the growth towards equilibrium of ^{230}Th rather than its unsupported decay may be used as a chronometer in this case. In general, the method should be applicable to any geological situation in which a precise disequilibrium is established at a particular time, and in which the total α-decay is dominated, aside from U, by one nuclide and its daughters.

Core V19-61 was obtained through the courtesy of Lamont-Doherty Geological Observatory, who received financial support from the Office of Natal Research and the National Science Foundation.

Light-driven, carrier-mediated electron transfer across artificial membranes

WE report that light-induced electron transport across artificial membranes mediated by electron carriers has been realised by photogeneration of the reducing species.

Quinone-type carriers achieve redox processes across membranes[2–4] and are involved in mitochondrial and photosynthetic electron and proton transport (ubiquinones, plastoquinones, vitamin K)[4–6]. They perform cotransport (symport) of two electrons and two protons through their reduced hydroquinone form. Ferrocene type carriers[4] operate by way of oxidation to the ferricinium cation.

Electron transfer experiments have been conducted in a cell in which an aqueous solution of a reducing agent (RED: sodium dithionite or ascorbic acid, reduction potentials $E_0 = -1.13$ and $+39$ V respectively)[7] is separated from an oxidising aqueous solution (OX: potassium ferricyanide, $E_0 = +0.36$ V)[7] by a diphenyl ether membrane supported on a Millipore filter and containing a suitable carrier molecule. The carriers used were either menadione (vitamin K$_3$; 2-methyl-1,4-naphthoquinone, NQ, $E_0 = +0.44$ V)[7] or dibutyl ferrocene (DBF, $E_0 = +0.23$ V)[8]. The electron transfer process is followed by monitoring the reduction of ferricyanide to ferrocyanide at 420 nm, where only the former absorbs. In the absence of carrier in the membrane no reduction is observed. When either NQ or DBF are dissolved in the membrane, ferrocyanide is formed in the OX phase showing that electron transfer occurs through the NQ/NQH$_2$ and DBF$^+$/DBF redox carrier systems (Table 1). The transport rate increases with increasing concentrations of NQ in the membrane although not linearly (Table 1, runs 3–6). The absence of leakage through the membrane was checked at the end of the experiments by ensuring that no iron hexacyanide had passed into the RED compartment.

Coupling electron transport to light irradiation should be possible in a system where irradiation would generate a reducing species which would then be able to transfer an electron to a carrier molecule through the interphase, but which would not itself cross the membrane. Methyl viologen (MV^{2+}, 1,1′-dimethyl-4,4′-bipyridinium chloride) seemed to be a suitable substance; it has been used in many physicochemical and biological (for example, in photosynthesis) redox studies. Reduction of the colourless oxidising form (MV^{2+}) gives a blue cation (MV$^{\cdot+}$) ($E_0 = -0.44$ V)[7], which is able to reduce quinones like vitamin K$_3$[2] and being monocharged should remain in the water phase. Furthemore, MV^{2+} may be photoreduced in aqueous solution by a photosensitised reaction involving visible light, a sensitising dye, proflavine (PF, $E_0 = -0.73$ V; $\lambda_{max} = 445$ nm), and an electron donor, ethylenediamine tetraacetic acid (EDTA)[9].

We have used this system (PF + MV^{2+} + EDTA) as the RED phase in transport experiments with menadione as the electron carrier in the membrane and ferricyanide in the OX solution, as in previous experiments. When the transport cell is kept in the dark no change in colour or in ferricyanide concentration was observed. When irradiated with visible light from a halogen lamp the RED phase turns rapidly blue, showing that MV$^{\cdot+}$ is produced, and the ferricyanide concentration decreases. If the light is turned off, the ferricyanide concentration levels off; on reillumination it continues to drop. No change in ferricyanide concentration is observed in the absence of menadione in the membrane. These results show that light-coupled electron transport has indeed been achieved by the photoactivated process shown in Fig. 1*a*. Table 1 (runs 10–13) and Fig. 1*b* show some typical experiments.

Table 1 Electron transport by carrier molecules across an artificial membrane in chemical (runs 1–9) and light-coupled (runs 10–15) redox systems

Run	RED (mM)			Carrier in membrane (mg)	Transport rate (μM × h^{-1})

7	Dit. 10			NQ(7.2)	24.7
8	Dit. 10			—	0
9	Asc. 10			DBF(7.2)	3.0
	PF (μM)	MV^{2+} (mM)	EDTA (mM)		
10*	40	1.0	20.5	NQ(6.9)	9.2
11*	0	1.0	20.7	NQ(7.2)	5.0
12*	0	0	20.0	NQ(7.3)	5.0
13*	0	0	0	NQ(7.3)	0
14*	54	1.0	20.5	NQ(7.5)	7.9
15*	0	0	20.5	NQ(7.2)	0

All experiments were performed at 25 C under argon in a cell consisting of three phases: RED, reducing aqueous solution (40 ml) membrane OX, oxidising solution (40 ml); the two aqueous solutions are stirred continuously. Membrane: 75 ± 3 mg carrier solution in diphenylether on a Millipore filter (cellulose nitrate 4 cm diameter, 500 Å holes). Carriers: NQ, 2-methyl-1,4-naphthoquinone menadione; DBF, dibutylferrocene. Runs 1, 2: OX, 5 mM potassium ferricyanide, 0.2 M potassium phosphate buffer at *p*H 7.05 in both RED and OX. Runs 3–8 and 10–15 OX, 10 mM potassium ferricyanide, 0.1 M potassium phosphate buffer at *p*H 7.0 in OX and at *p*H 6.2 (runs 3-6) or *p*H 7.0 in RED. Run 9: OX, 20 mM potassium ferricyanide, 0.1 M sodium citrate buffer at *p*H 6.37 and 1.2 mM sodium bromide in both RED and OX. Asc., ascorbic acid; Dit, sodium dithionite; PF, proflavine; MV^{2+}, methyl viologen dichloride; EDTA, ethylenediamine tetraacetic acid. In the photoreduction experiments (runs 10–15) the concentration of each component of the RED phase is indicated.

*Light source: runs 10–13: 150 W halogen lamp; runs 14 and 15: 200 mW argon laser at 476.5 nm.

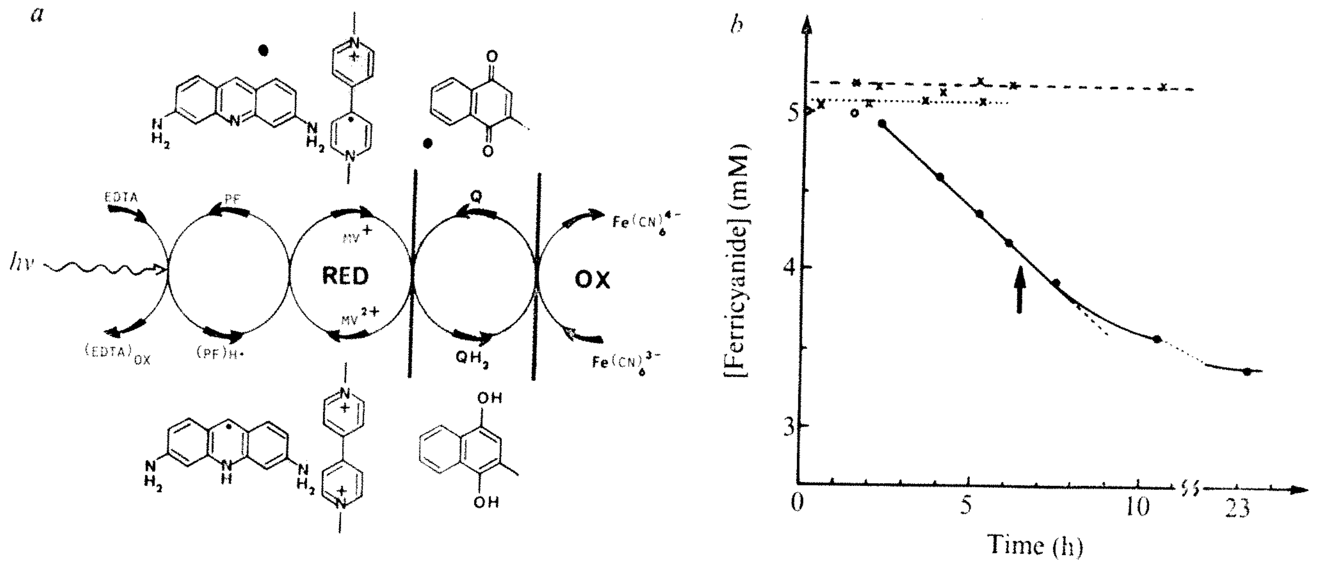

Fig. 1 *a*, Diagrammatic representation of the light coupled transport of electrons across a membrane. The reducing species in the RED aqueous phase at left is the radical cation $MV^{\cdot +}$ produced via proflavine (PF) sensitised photoreduction of methyl viologen MV^{2+} by the electron donor EDTA. The membrane contains vitamin K_3 as carrier molecule and the oxidising agent in OX is ferricyanide. *b*, Typical experiments showing the variation in ferricyanide concentration in the OX phase in three conditions: in the dark (– –); under irradiation but with no menadione in the membrane (. . .); with the complete system shown in Fig. 1*a* (—). In the latter experiment the conditions were: RED: 50 μM PF + 5 mM MV^{2+} + 10 mM EDTA in 0.1 M phosphate buffer at *p*H 6.5; membrane: 6.9 mg menadione in 72 mg diphenylether on a Millipore filter; OX: 5 mM potassium ferricyanide in 0.1 M phosphate buffer at *p*H 7.0. From the linear section of the curve the transport rate is 7.1 μM h^{-1}; the light was switched off at the point indicated by the arrow; the rest of the curve corresponds to the ferricyanide reduced by the $MV^{\cdot +}$ and the hydroquinone present at the time where the light was switched off.

The efficiency of the photocoupled electron transport (run 10) is comparable with that of the previous chemical redox systems. A problem with this system is, however, that the RED phase slowly bleaches in the course of the experiment but addition of fresh PF restores the original colour. Because bleached solutions continued to effect electron transport, control experiments were performed. The transport rate is the same in the absence of either PF alone (run 11) or of both PF and MV^{2+} (run 12), being half the rate of run 10. Thus the complete system is necessary for highest efficiency and MV^{2+} has no effect in the absence of PF. With EDTA alone, photoactivated electron transport still occurs (run 12), so experiments were conducted under irradiation with an argon laser at 476.5 nm where menadione does not absorb. The transport rate, although similar to that obtained with white light when the whole RED system is present (run 14), now becomes zero with only EDTA in the RED phase (run 15). This confirms that the naphthoquinone carrier may indeed be photoreduced by EDTA under visible light irradiation with the halogen lamp.

We have demonstrated that electron transport processes across artificial membranes using suitable carrier molecules can be coupled to light irradiation. The search for a more stable photosystem (for example metal cation complexes) may lead to applications in energy storage. On the other hand, coupling of either chemically-induced or photoactivated electron transport to cation (other than proton) symport and anion antiport may be envisaged, providing models for biological systems[5] as well as new chemical processes and potentially useful transport cells.

Yes, Kakangari is a unique chondrite

The Kakangari chondrite seems to be the only representative so far recognised of a new class of chondrites. Mason and Wiik[1] noted a similarity between Kakangari and Mokoia (C3(V)) in bulk chemical composition when expressed on a volatile-free basis, but pointed out that the higher metal content of Kakangari suggests a relationship between it and Renazzo (C2). Recognising that Renazzo contains much less troilite and much more FeO than Kakangari, however, they concluded that Kakangari was a new type of carbonaceous chondrite, more reduced than the others. Graham and Hutchison[2] emphasised the chemical similarity between Kakangari and the ordinary chondrites, apart from its higher S content, and posed the question, "is Kakangari a unique chondrite?". Using the data of Mason and Wiik[1] as well as their own electron microprobe data, they noted that Kakangari is closer in total Fe content to the L- than the H- group chondrites but that its oxidation state lies between those of the H- and E- chondrites. Clayton *et al.*[3,4] were able to distinguish Kakangari from the ordinary chondrites on the basis of oxygen isotopes. On a three-isotope diagram, Kakangari plots with the anomalous stony-iron meteorites Bencubbin and Weatherford along an extrapolation of the apparent mass fractionation line defined by the low-temperature hydrous silicate phases of three C2 chondrites. We have now analysed a 17.1-mg piece of Kakangari for 20 elements and can answer Graham and Hutchison's question in the affirmative.

We used the INAA techniques described in previous publications from this laboratory[5,6]. The standard pot, SP[7,8], was used as a standard for most elements. Their concentrations were taken from Perlman and Asaro[8]. The

Table 1 Elemental abundances in the Kakangari meteorite

Element	Concentration (p.p.m., unless otherwise indicated)
Na	6,938 ± 8
Sc	8.70 ± 0.01
Cr	3,590 ± 10
Mn	2,700 ± 40
Fe	21.1 ± 0.1 %
Co	394 ± 1
Cu	170 ± 1
Zn	171 ± 5
Ga	9.7 ± 0.6
As	1.6 ± 0.1
Sb	0.18 ± 0.02
La	0.36 ± 0.02
Ce	1.1 ± 0.1
Sm	0.198 ± 0.009
Eu	0.088 ± 0.003
Yb	0.27 ± 0.02
Hf	0.14 ± 0.03
Os	1.13 ± 0.07
Ir	0.711 ± 0.001
Au	0.206 ± 0.001

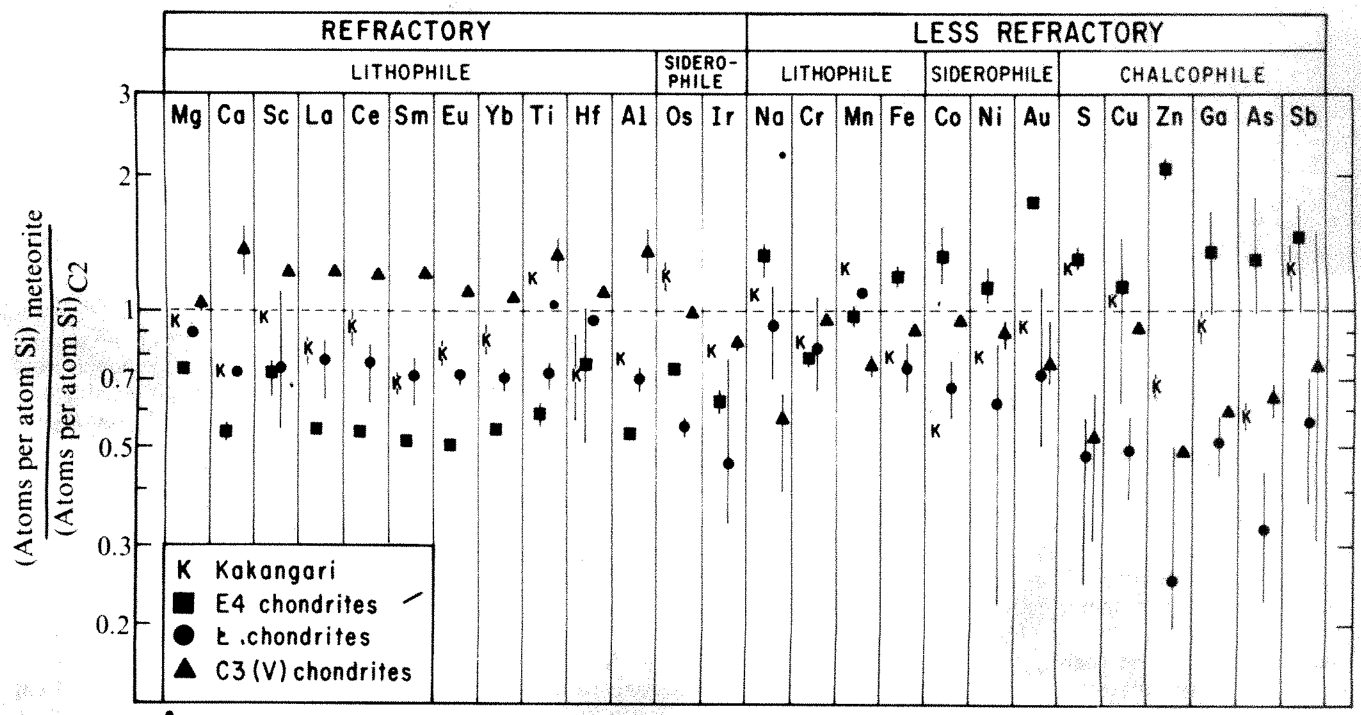
concentrations of Os, Ir and Au in Kakangari were determined from chemical standards which had been run in previous irradiations. The specific activities of ^{191}Os, ^{192}Ir and ^{198}Au at the end of the Kakangari irradiation were calculated from their values in previous irradiations by correcting for differences in neutron fluence using ^{46}Sc in SP. The results are shown in Table 1, along with errors based on 1σ counting statistics for sample and standard. Our data for Fe, Na and Mn are within 6–12% of the wet chemical data of Mason and Wiik[1]. These small differences probably reflect a small amount of sample heterogeneity. Our Cr content for Kakangari is a factor of 2.8 higher and Co a factor of 2 lower, however, than the concentrations reported by Mason and Wiik[1]. This may be due to analytical difficulties in the wet chemical determination of low concentrations of these elements. The Ti value of Mason and Wiik[1] may be similarly affected[9].

In order to compare Kakangari to other meteorite groups, all available elemental concentration data from this work and Mason and Wiik[1] were converted to silicon-normalised atomic abundances. The most similar groups, C2, C3(V), L and E4 chondrites, are represented in Fig. 1, along with Kakangari.

The less refractory lithophile and sidero phile elements are at about the same levels in Kakangari and the L-chondrites, but sulphur is enriched in Kakangari by a factor of 2.7 relative to the average L-chondrite and the chalcophile elements Cu, Zn, Ga, As and Sb are enriched by a factor of 2.1 ± 0.2 (1σ standard error). Close inspection of Fig. 1 shows also that the abundances of most refractory elements in Kakangari plot either slightly above their concentration ranges in L-chondrites or at the extreme upper limits of those ranges.

While similarities can be found occasionally in the concentration levels of some elements between Kakangari and either the E4, C2 or C3(V) chondrites, pronounced differences do exist between Kakangari and these other meteorite classes. Kakangari is higher by a factor of 1.47 ± 0.08 than E4 chondrites, lower by a factor of 0.86 ± 0.04 than C2 chondrites and lower by a factor of 0.72 ± 0.04 than C3(V) chondrites in refractory lithophile elements (all uncertainties are 1σ standard errors). Among the less refractory elements, Kakangari is higher than E4, C2 and C3(V) chondrites in Mn abundance, lower than these classes in Co content and intermediate between C2 and C3(V) chondrites in Zn concentration. Note particularly the substantial depletions of Co, Zn and As in Kakangari relative to the C2 chondrites.

Fig. 1 Si-normalised atomic abundances for Kakangari, E4, L and C3(V) chondrites, relative to C2 chondrites. Data for E4, L and C3(V) are shown with their ranges when available. The Kakangari data are shown with their 1σ error bars when the uncertainty is larger than the symbol. The data for E4, L, C2 and C3(V) chondrites are from the following sources: Na: E4, L[10], C2, C3(V)[11]; Mg, Al, Si, Ca, Ti, Mn, Fe: E4, L[12], C2[12,13], C3(V)[12,14]; S: E4, L, C2, C3(V)[15]; Sc, Cr: E4, L, C2[10], C3(V)[6]; Co: E4[16], L[17], C2[10], C3(V)[6]; Ni: E4, L, C2[18], C3(V)[19]; Cu: E4[16], L[20], C2, C3(V)[10]; Zn: E4[21], L[20], C2[22], C3(V)[23]; Ga: E4[16], L[20], C2[24], C3(V)[23]; As: E4[16], L, C2, C3(V)[17]; Sb: E4[16], L[17], C2[22], C3(V)[19]; La, Ce, Sm, Eu, Yb: E4, C2, C3(V)[25], L[26]; Hf: E4[27], L, C2[28], C3(V)[29]; Os: E4, L, C2, C3(V)[30]; Ir: E4, L[31], C2[22], C3(V)[19]; Au: E4[32], L[20], C2[22], C3(V)[19].



Our trace element data thus confirm the conclusion of Mason and Wiik[1] and answer the question posed by Graham and Hutchison[2]. Kakangari is a unique chondrite in that its bulk chemical composition does not match that of any single known class of chondrites.

We thank R. Hutchison for the specimen of Kakangari and E. Anders and R. N. Clayton for discussions. This research was supported by grants from the National Aeronautics and Space Administration and the Alfred P. Sloan Foundation.

Microbiota under Antarctic ice shelves

WHETHER or not life can exist far from the open sea beneath the permanent ice shelves of Antarctica is not known, but there are three opinions. (1) A biota cannot exist at all because of the absence of surface primary and secondary productivity[1]. (2) A biota exists but with specialisations unique to life in the absence of surface productivity and in isolation under an ice shelf[1]. (3) A typical Antarctic biota exists under any Antarctic ice shelf because currents are surely present that could carry food to it[2]. Evidence supporting any of these views is unreliable. On the Ross Ice Shelf, samples taken through cracks 22 and 28 km from the open sea and in a newly calved area 8 km from the former ice front yielded rich benthic faunas but no floras[3,4]. Plant life was presumably restricted by the lack of light coming through the ice. Some of the more common species of animals at nearby McMurdo Sound were not found in the samples, indicating that there was a possibility that conditions under the ice precluded them. Such differences, however, are common in Antarctic shallow-water areas, and can be due to local substrate differences, recent grounding of ice, or sampling bias dependent on the size and penetration depth of the sampler[5]. The Ross Ice Shelf locations are so close to the open ocean that typical benthic communities might live there. At George VI Sound, marine fish whose stomachs contained several species of invertebrates were caught through a proglacial lake adjacent to the ice shelf 100 km from the nearest open water[6]. These animals were interpreted as evidence that a marine biome occurs under the entire shelf[6]. However, we describe here a microbiota from the George VI Sound occurrence that indicates that the fauna there may also be unique because it resides in a situation not typical of the entire ice shelf. Available evidence thus does not support any opinion.

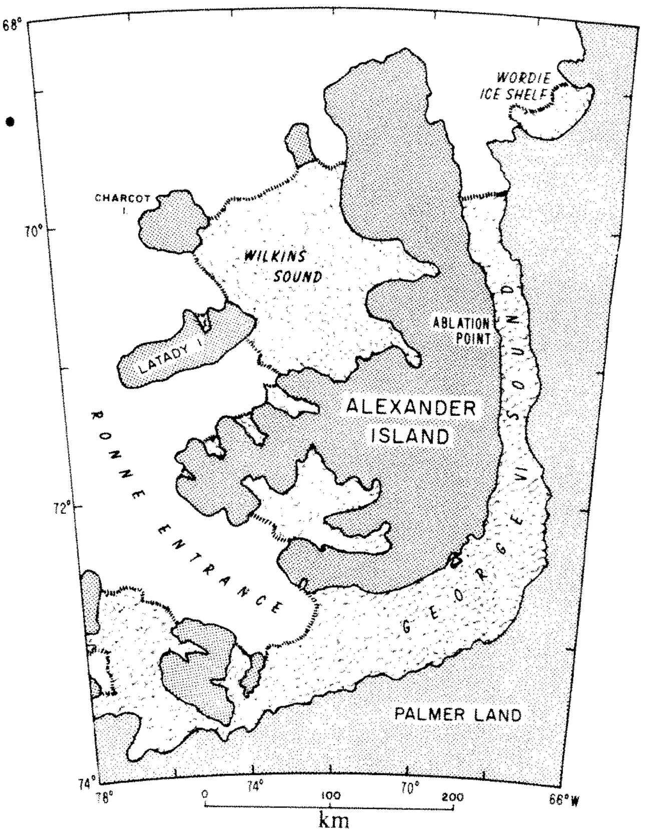

Fig. 1 George VI Sound region and Ablation Valley near the base of the Antarctic Peninsula. Ice shelves are shown in light stipple. Map from ref. 7.

George VI Sound is approximately 475 km long and 20 to 60 km wide, and is open on both ends to the Bellingshausen Sea (Fig. 1). It is covered by permanent ice varying between 100 and 500 m thick[8], but there are a few holes and cracks in it through which samples may be obtained. Mud samples collected in the proglacial lake at Ablation Valley (Fig. 1), where the fish were caught, yielded an abundant microbiota. As described by Heywood and Light[6], the lake, 5 by 4 km in size, lies adjacent to the sound and is intruded for 3.4 km

by the ice shelf. It is covered by ice, 2.5–4.5 m thick, throughout the year. Light can penetrate this thickness of ice. The lake is over 117 m deep, but only below 66.25 m is there marine water. Tidal fluctuations in the marine layer show that it is connected with the seawater of the sound[6].

The microbiota (Table 1) includes 10 species of foraminifera (Fig. 2) and at least 11 species of diatoms found in a marine sample at 68.5 m and one diatom species from a freshwater sample at 47 m. Mixing of the biotas from these water layers was not apparent in our samples. All foraminifera and diatom species are benthic. The diatoms and foraminifera are nearly perfectly preserved and quite abundant; most of the diatoms still retain some pigment. The specimens seem to have been alive or recently dead when collected. No other microorganisms possessing hard parts were found. We have found all of the species, including the fish and invertebrates, farther north in ice-free waters along the Antarctic Peninsula[5,9]. Centric and pennate diatoms have also been found in seawater present in crevasses on the Ross Ice Shelf 550 km from the open Ross Sea[10].

Our results reinforce previous conclusions[8] that an abundant and diverse Antarctic marine biota lives at Ablation Valley. Heywood and Light[6] concluded that the productivity they recorded for the freshwater layer was too low to support fish populations. The abundance of marine diatoms from lower levels, however, indicates that there is also marine primary productivity, probably sufficient to sustain higher trophic levels.

The microbiota we record from the proglacial lake can be interpreted in either of two ways: (1) it may indicate that there is indeed a diverse and rich biome under the George VI Ice Shelf as postulated[2,6], in which case it would have to be supported by a food supply carried there by currents[2] passing through the sound; or, (2) it may mean that the biota at Ablation Valley is atypical of the sound as a whole because the marine primary productivity may support a biological oasis where light penetrates through the thin ice cover of the proglacial lake. Although some diatoms perhaps could live heterotrophically under a thick ice cover, we conclude that the second possibility cannot be eliminated. Thus, in spite of a few occurrences near ice fronts and in the unique situation at Ablation Valley, there is still no unequivocal evidence of what a sub-ice shelf biome might be like.

We thank Drs R. B. Heywood, Charles Swithinbank, and Nigel Bonner of the British Antarctic Survey, Cambridge, UK, for providing information and samples (collected during the 1973–1974 austral summer) from George VI Sound, and Dr T. E. DeLaca, University of California, Davis. This work was supported by NSF grants.

First Devonian platyspermic seed and its implications in gymnosperm evolution

IN the course of an investigation of fossil plants from the late Devonian rocks of Kiltorcan in southern Ireland obtained by re-excavation of the site earlier this year, we have discovered several seeds with features which contribute to the understanding of early gymnosperm evolution. The fossil flora of Kiltorcan has been known for more than a century[1], and includes the well-known and widespread late Devonian genera *Archaeopteris* and *Cyclostigma*. In addition, Johnson[2] briefly described and illustrated several oval bodies which he regarded as seeds, and to which he gave the name *Spermolithus devonicus*. His figures were at a small scale and rather uninformative, and most later workers discussing early evidence of seed plants have either been unaware of his claim, or make no reference to it. The only reference to *Spermolithus* known to us is Arnold's[3] justifiable comment that "whether it is a seed or spore case is unknown to us". In spite of the limitations of their state of preservation, we believe that the seeds we have found represent not only the earliest seed plants known from the British Isles, but also the earliest seeds with apparently platyspermic symmetry. In view of their closeness in age to the earliest generally accepted seed, *Archaeosperma*, of radiospermic character, we believe that this favours a more or less synchronous origin of radiospermic and platyspermic gymnosperms. This suggests that these two seed lineages have been separate since their inception, rather than having had a single evolutionary origin followed by rapid divergence within the Carboniferous.

Knowledge of early seed plants has grown significantly in the past decade[1-7], and has an important bearing on the interpretation of their early evolution. The most convincing record of a seed of Devonian age is that of *Archaeosperma* Pettitt and Beck[5] from the North American Famennian. This seed, although a compression, has been shown to have at least four integumentary lobes making it unmistakably radiospermic. Long[1,8,9], in his extensive researches into early Carboniferous (Tournaisian) seed plants, has found both platyspermic and radiospermic seeds with well preserved structure. He has suggested[4] that the platyspermic condition evolved from radial ovules with only two integument lobes, showing that in the early stages of platyspermy they retain the radial symmetry at the nucellar apex. This would be consistent with a single origin for seed plants in a radiospermic Devonian ancestor such as *Archaeosperma*. Other authors[10-11] acknowledge the possibility of a polyphyletic origin of gymnosperms. Our discovery supports such a hypothesis.

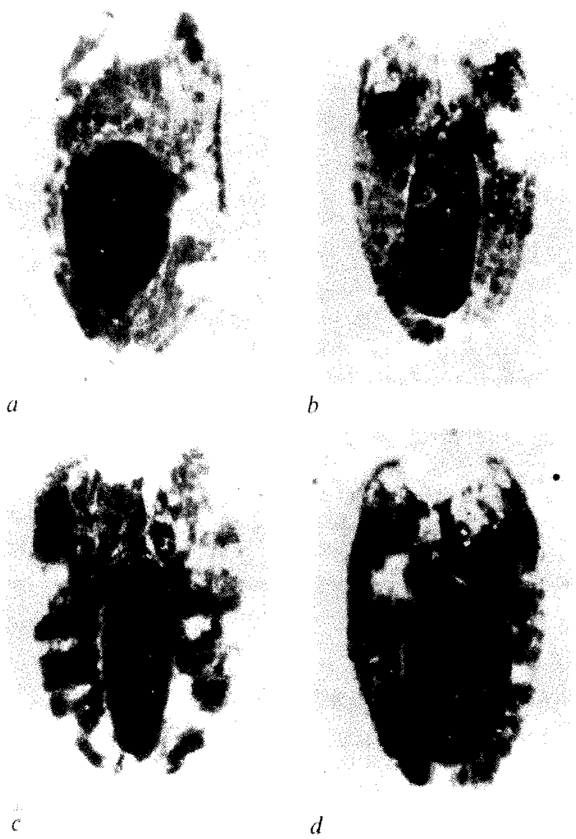

Fig. 1 Four seeds, cf. *Spermolithus devonicus* Johnson preserved as chloritised compressions from the Upper Devonian Kiltorcan Beds, Kiltorcan "Old Quarry", County Kilkenny, Eire (× 14, photographed under xylene). The assumed apical (micropylar) embayment is uppermost in each case; a basal notch is discernible, for example in (*d*). The dark central structure is interpreted as a megaspore. A possible nucellar apical expansion (or micropylar canal infill) is discernible in (*c*) and (*d*).

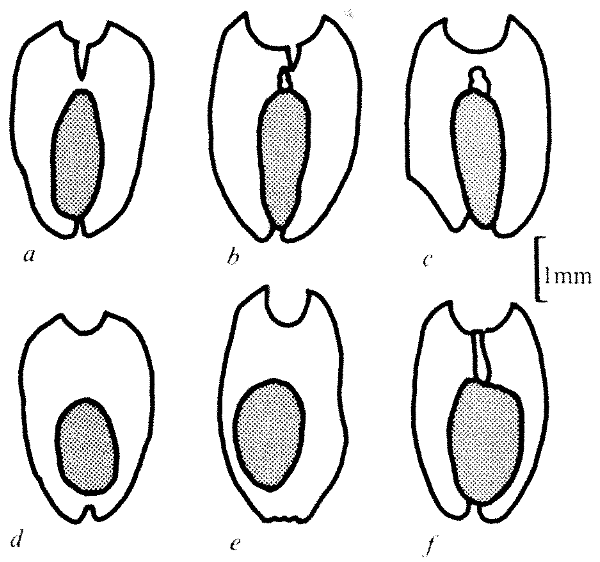

Fig. 2 Outline drawings of six specimens of seeds, cf. *Spermolithus devonicus* Johnson drawn from photographs. The scale bar is 1 mm. These show the consistent presence of the apical embayment with lateral lobes. The megaspores (stippled) show greater variation in size and shape than the enclosing structure, a characteristic feature of seed-megaspores in Palaeozoic seeds.

There are several records of seed-like bodies from the late Devonian or basal Carboniferous[12-15] of which *Condrusia minor* Stockmans[13] and *Moresnetia zalesskyi* Ananiev[16] are of particular interest. These have a distinct bicornute shape, implying platyspermy, but far too little is known about these bodies even to state definitely that they are seeds.

The discovery of the assemblage of seeds at Kiltorcan makes some contribution to this controversy of seed plant origins. The Kiltorcan fossil plant material is in an unusual, and in some ways unsatisfactory, state of preservation. The plants were evidently initially preserved as coalified compression fossils[17] in which the coaly substance was subsequently entirely replaced by a chloritoid mineral[18]. Although the resulting fossils make striking museum specimens, they are not amenable to oxidative maceration, which is the normal means of making microscopic (cuticle) preparations of fossil plant compressions. Immersion of the fossils in xylene and observation under strong incident lighting, however, reveals limited information on their internal organisation (Fig. 1).

It is critical to our case to establish that our fossils (Figs 1 and 2) are not merely seeds but that they are of platyspermic organisation. The possibility of discriminating reliably between radiospermic and platyspermic seeds, even when compressed in fossilisation, was first advanced convincingly by Arber[19]. The 30 seeds showing more or less intact outline that we recovered from Kiltorcan show a uniformity of size and shape consistent with plant propagules shed in a mature condition; in particular, they regularly show an eccentrically-placed dark oval body (stippled in Fig. 2) close to a small notch and a larger, presumably apical, embayment with two associated lobes. By analogy with better preserved seeds, we can interpret the embayment as the site of the micropyle (as in the widespread Carboniferous platyspermic seed *Samaropsis*) and the dark inner body as the megaspore (as in *Menaisperma*[20] where maceration of the inner body shows it to be a megaspore surrounded by the nucellus), and in some of our seeds there is an indication of what may be a free nucellar apex or micropylar canal (Fig. 2*b*, *c*, and *f*). This interpretation of the inner body is supported by its variation in both size and shape (Figs 1 and 2). Other workers[20,21] have demonstrated such variation in several well-preserved fossil seeds. The consistent occurrence of the apical lobes and intervening embayment rules out the possibility that we are simply seeing a random fracture plane passing through a broad micropylar opening (such as might occur in a compression state of the radiospermic *Stamnostoma*). We believe that the generally cordate form of our seeds aligns them with typical Carboniferous members of the genus *Samaropsis*, particularly *S. crassus* and *S. subacuta*[19]. On this interpretation, these Kiltorcan seeds are regarded as lying with their major transverse axis in the bedding plane as they became buried.

Provisionally, we assign our seeds to Johnson's species *Spermolithus devonicus*. His seeds, so far as can be judged from his photographs and brief description, show similar features to ours in appearing to have the oval shape, apical embayment, a central body and approximately similar size. A search for Johnson's original figured (type) material in museum and university collections in Dublin and elsewhere has been unsuccessful.

We thank Professor C. H. Holland and his colleagues in Trinity College, Dublin, and T. Roche, S. D. Canning and J. Quinn and their staff at Roadstones Limited, for help with the re-excavation of Kiltorcan 'Old Quarry'. The work was supported by grants from the Central Research Fund of the University of London and the Research Fund of University College, Bangor.

Mouth gaping as an effective thermoregulatory device in alligators

GAPING is a characteristic activity of several species of crocodilians in which the animal lies ashore with its mouth held open for prolonged periods[1-4]. It has stirred the interest of humans for millennia: gaping is depicted in Egyptian papyri and was mentioned in the writings of Herodotus and Pliny. Today interest continues in gaping and other aspects of behaviour in these large reptiles, the last of the subclass Archosauria, the group of reptiles that included the dinosaurs[1,5]. Gaping is a complex habit that involves variable degrees of mouth closure and sometimes includes rhythmic gular movements. Behavioural observations have suggested that gaping is a thermoregulatory response[3,4] but until now physiological studies have been inconclusive. Initial reports[6] stated that gaping was effective in cooling young Nile crocodiles (*Crocodylus niloticus*) but a recent experiment on *Caiman crocodylus* indicated that this behaviour had no thermoregulatory significance[7]. Here we present evidence from controlled laboratory and field experiments that gaping is an effective mechanism for reducing head temperatures of alligators (*Alligator mississippiensis*). Gaping reduced the rate of heat gain by the heads of small and large alligators when these animals were exposed to high light radiation loads at moderate air temperatures. The magnitude of this effect increased with size. Gaping had little effect on body temperature and did not reduce the final equilibrium temperature of the head.

Head, palate and body temperatures were measured (Cu–Co thermocouples) in three alligators under controlled conditions in an environmental chamber. Alligators were anaesthetised with ketamine hydrochloride[8] and a 38-gauge thermocouple inserted in the head to a depth of 1.5 cm in the upper temporal fossa, anterior to the adductor externus profundus muscle. Palate temperature was measured with a 38-gauge thermocouple placed under the skin below the palatal fenestra and body temperature was measured with a 24-gauge thermocouple inserted through the cloaca into the colon to a depth of 10 cm. Incisions were sealed with glue (Eastman 910) and animals were allowed to recover for a period of 24 h before being tested. Each alligator was tested twice, once with its mouth closed and once with its mouth propped open at an angle of 35° to simulate the gaping posture. Alligators were placed in an environmental chamber at an air temperature in the range of 20 to 23 °C and heated by radiation and conduction until body temperature reached equilibrium. Sodium vapour lights were used to give high visible flux, and floor temperatures were controlled at an elevated level. Wind speed was 190 cm s^{-1} and radiation absorbed by the alligators was 0.76 calorie cm^{-2} min^{-1}, about that of mid-morning on a clear day.

In all three cases the heads of alligators with their mouths propped open heated at a lower rate than those of alligators with their mouths closed (Table 1). This was indicated by the determination of time constants. Time constants for the equilibrium of head temperature for the open mouth condition (τ_O) were greater than those for the mouth closed state (τ_C), ranging from 1.4 times greater for the smallest animal to 2.1 for the largest. The time constants for the rate of heating of the body (that is, cloaca) with the mouth open were similar to those with the mouth closed.

We conducted an additional experiment on a large adult (total length 2.92 m, estimated weight 100 kg) in the field. The animal was captured during October, 1975 at the Savannah River Ecology Laboratory (Aiken, South Carolina). Thermocouples were implanted as described previously and after a 24-h recovery period the alligator was placed in the sun with its mouth propped open (20° gape) at mid-morning on a clear day. The animal was not heated to its equilibrium temperature since this temperature would have been above its lethal limit. After 160 min, head temperature had risen from 23.2 to 32.7 °C and body temperature had risen from 23.4 to 26.3 °C. The next day the alligator was heated again in similar environmental conditions, but with its mouth closed. Now after 160 min head temperature went from 23.1 to 35.0 °C and body temperature rose from 23.1 to 25.2 °C. Body temperature rose 2.9 °C on the first day and 2.1 °C on the second day. This indicated that although environmental conditions seemed similar, this alligator actually had a lower net heat input to the body during the mouth closed test. Despite this fact, head temperature rose 11.9 °C with the mouth closed as compared to 9.5 °C with the mouth open. This strongly suggests that gaping was important in reducing the rate of heat gain to the head region. Thus it seems that the effect of gaping on a 100-kg alligator was similar to that on animals ranging in size from

Table 1 Temperatures and time constants for alligators heated under controlled environmental conditions with their mouths open and closed

*τ_o, Time constant for mouth open; τ_c, time constant for mouth closed. A thermal time constant for a linear first-order system is the time required for the temperature of an object to travel $(1 - e^{-1})$ or 63.2% of the way to the applied temperature. The smaller the time constant the faster the temperature change. A standard heating- or cooling-curve experiment is an example of a linear first-order system. In this case body temperature changes as a function of time: $T = T_f + (T_0 - T_f)\, e^{-t/\tau}$ where T is body temperature (°C), T_0 is initial body temperature (°C), T_f is final body temperature (°C) and t is elapsed time (min). The parameter τ is the time constant. An alligator coming into equilibrium with heat sources and sinks in a complex environment can be approximated as a linear first-order system[9,10].

2.2 to 14.5 kg in weight, since rates of heat gain by the head were reduced in all cases when gaping was simulated. Gaping was an effective thermoregulatory mechanism in the environmental conditions tested in this study.

These results are expected from energy budget theory[11,12]. Exposure of the moist mucous membranes of the mouth during gaping would result in evaporative cooling. The rate of cooling would increase at low relative humidity and in the presence of a breeze. The mechanisms by which heat is transferred from the brain region to the mouth where it is dissipated during cooling are not known at present. Heat may be transferred by direct conduction through the bony skull and/or by blood circulation. Transfer of heat may also be occurring between the head and body by way of the circulatory system as has been demonstrated for *C. johnstoni*[13]. However, head–body temperature differences in reptiles can result from physical factors independent of the animal's control[14]. Therefore, definitive comments on mechanisms of heat transfer within the alligator cannot be made until further investigations of vascular patterns, conduction pathways and the mechanics of heat flow within the head have been carried out.

Though physiological studies under controlled conditions clearly indicate that gaping is a potentially useful mechanism for controlling heat gain of the head region in these animals, further studies are needed to define the importance of gaping in wild alligators. We expect that gaping would be most effective in spring, autumn and possibly winter in portions of the alligator's range in which it does not hibernate. These are times when alligators are exposed to cool water and air temperatures and should rely extensively on basking to raise their body temperature above ambient[15]. Gaping would reduce heat gain by the alligator's head and allow the animal to continue basking to allow its body temperature to continue to rise towards preferred levels. Then the alligator could retreat to the water to avoid over-heating. Gaping would be most effective in large alligators since their high heat storage capacity would require that they bask for long periods of time in order to raise their body temperature a few degrees.

This research was supported by an ERDA grant to J. R. S., a Sigma Xi research grant to P. D. and Oak Ridge Associated Universities travel grants to J. R. S. and P. D. Use of alligators was under the terms of a Federal Endangered Species Permit held by J. R. S. We thank J. W. Gibbons and J. Coker for their help.

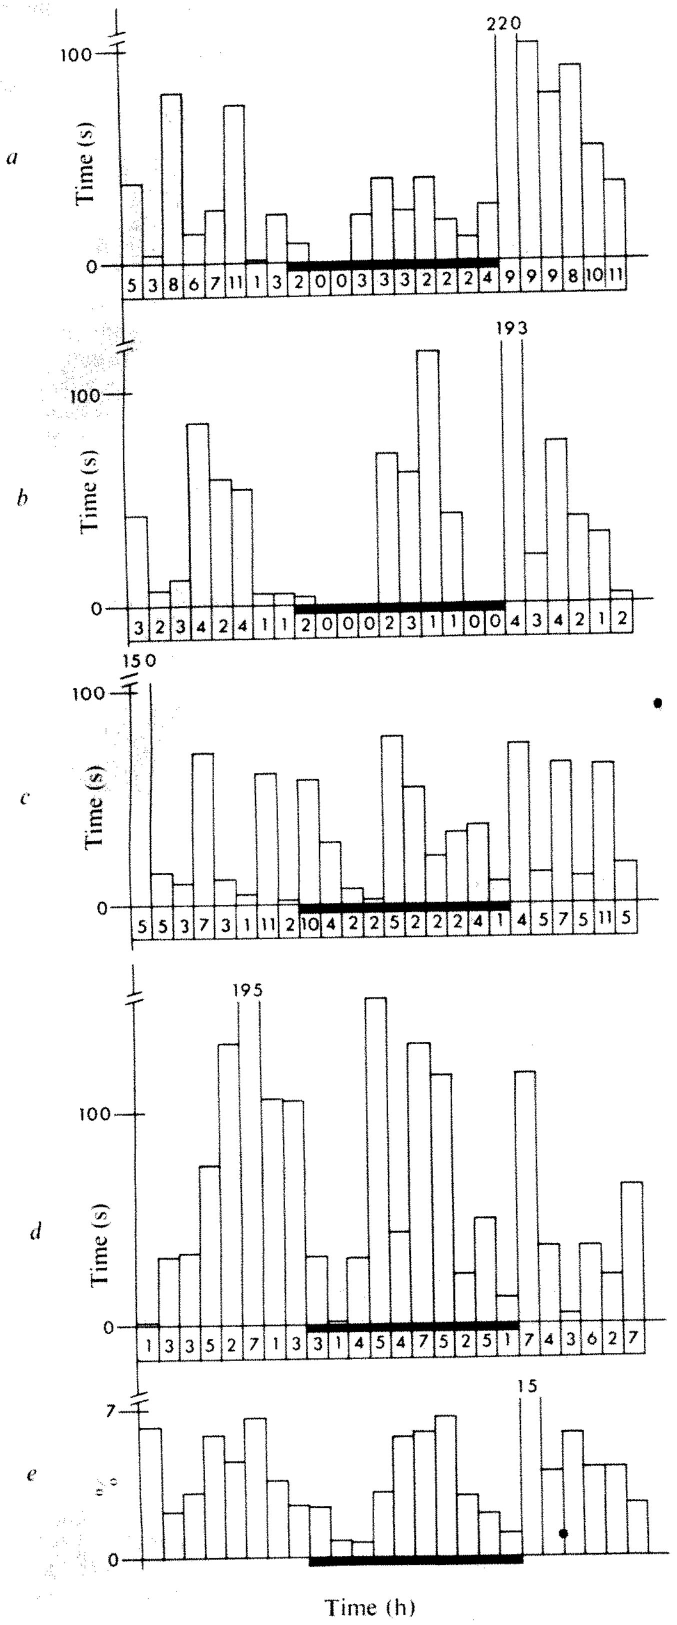
22-kHz calls by isolated rats

CALLS of about 22 kHz occur during two kinds of social interaction among rats, *Rattus norvegicus*: they are produced by submissive animals in agonistic encounters[1] and by males after ejaculation[2,3]. I have now discovered that calls of similar structure regularly occur without social stimulation and in a daily pattern controlled by the light–dark cycle. Such 'spontaneous' 22-kHz calls may help in the maintenance and development of other behaviour patterns.

The experiments reported here mainly involved round-the-clock recording of calls made by socially isolated, adult Wistar rats. Before observation each animal was entrained for at least 1 month to the light–dark schedule under which it was observed. During observation each animal was kept alone in an unused, quiet storeroom. A daily check was made on food, water and the operation of the lights, and vaginal smears were taken from the females. Calls were monitored with a bat-detector tuned to 23 kHz. This receiver produces an audible output signal in response to an ultrasonic input signal within 2–3 kHz of the frequency to which the receiver is tuned. Its output was continuously recorded on slow-moving magnetic tape which was periodically reviewed at a higher speed. Bouts of calls (groups of calls with a maximum interval between calls of 0.1 h) were replayed at the original speed, and the amount of time



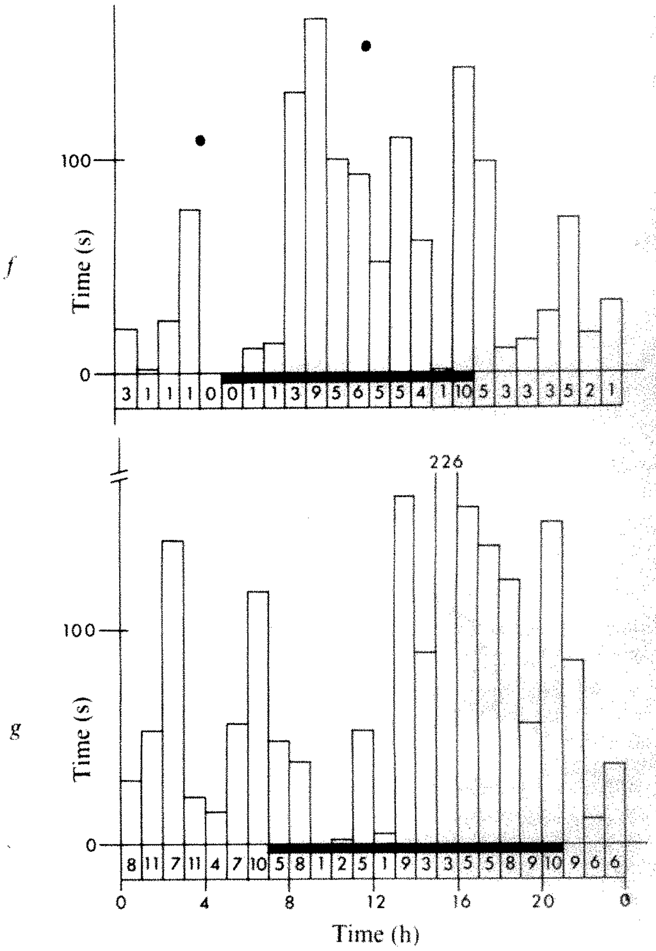


Fig. 1 Distributions of calling by six rats. Each column represents the total amount of calling(s) in that hour, summed over all days of observation. In hours in which this amount exceeded the maximum value on the ordinate, the column is topped with a number which is the amount observed in that hour. The total number of bouts in each hour and the hours of darkness are indicated below the abscissa. Hour 0 was midnight for all animals. *a*, An intact female with a 5-d oestrous cycle, observed for 20 d. *b*, An intact female with a 4-d oestrous cycle, observed for 12 d. *c*, An ovariectomised female, observed for 30 d. *d*, A male, observed for 7 d. *e*, Mean distribution of calling by animals *a* to *d* above, which were on the same 14:10 light–dark cycle; each column is the mean of the four individuals when calling for that hour is expressed as a percentage of the individual's total amount of calling. *f*, An intact female with a 4-d oestrous cycle, observed for 14 d on a 12:12 light–dark cycle. *g*, An intact female with no regular oestrous cycle, observed for 27 d on a 10:14 light–dark cycle.

spent calling was manually recorded on a cumulative timer. Sometimes the animals were also monitored with a second bat-detector tuned to 25 kHz, the output of which was recorded on a second channel of the tape recorder. This expanded the frequency range over which calls could be detected, and provided a convenient method for estimating the frequency of a call. The frequency of almost all calls was between 25 and 22 kHz. For consistency with other authors[2,3], these sounds are referred to as '22-kHz calls'.

Animals usually produced a number of calling bouts in each 24-h period. Within and between animals these bouts varied in duration (from less than a second to several minutes) and in the times when they occurred. Over a period of days, however, the distribution of time spent calling followed a pattern which was consistent for all animals regardless of their hormonal or environmental conditions (Fig. 1): the amount of calling was least in the early hours of darkness (not always the first hour), rose to a peak in the middle of the dark period, and declined towards the end of this period. When there was a 10-h dark period the decline ended abruptly in the first hour of the light period; with longer dark periods the decline ended in the last hour of darkness. There was much individual variation in calling through the rest of the light period, although there was a tendency for calling to decline gradually and then to peak again several hours before dark. Distributions *a*–*d* are highly similar ($W=0.581$, Kendall coefficient of concordance; $P<0.01$) between the onset of darkness and the peak of calling at its offset. The similarity is not as great for the entire 24-h period ($W=0.377$, $0.10>P>0.05$). The distribution of calling bouts is similar to the distribution of time spent calling (Fig. 2).

The lighting schedules of different animals were such that calling by some animals was least at hours (in real time) when calling by other animals was high. For example, in hour 18–19 (Fig. 1) calling was high for the four animals in *e*, very low for animal *f* and intermediate for animal *g*. This indicates that environmental factors other than the light–dark cycle did not influence calling.

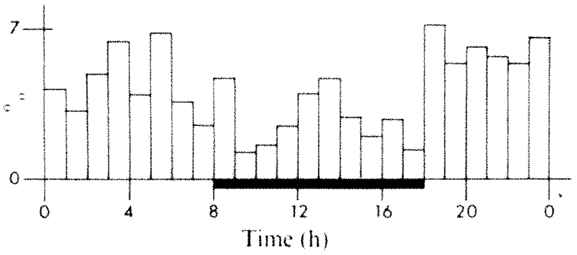

Fig. 2 Distribution of numbers of calling bouts for the four animals on the 14:10 light–dark cycle (Fig. 1, *a–d*). Each column represents the mean of the four individuals when the number of bouts in that hour is expressed as a percentage of the individual's total number of bouts.

Because stressful stimulation, such as electric shock or rough handling may also elicit calling[2], the stress of social isolation might have been responsible for the 'spontaneous' calls. But calling frequently occurs in lactating females caged with their young, in animals individually caged next to each other, and in colonies of both laboratory and wild rats (unpublished findings). During most of these latter observations there were no overt signs of agonistic or sexual behaviour, which suggests that 'spontaneous' calling is normal for grouped as well as isolated rats.

'Spontaneous' calling is evidently associated with inactivity and rest. Activity and feeding of rats is intense in the early hours of darkness, which is when calling is least. Furthermore, a number of authors report that feeding and activity then subside and later rise to a second peak a few hours before the onset of light[4–8], a common pattern among nocturnal mammals[8]. This is the obverse of the pattern in 'spontaneous' calling, the peaks of which could all be associated with times of rest when animals are preparing for, or recovering from, activity peaks during darkness. 'Spontaneous' calls may be associated with sleep. On some occasions I simultaneously observed the behaviour and calling of lactating females with their litters. Nearly always the female was apparently asleep when calling occurred. Furthermore, the EEG pattern during post-ejaculatory calling is identical to the pattern during sleep[3], and the overt behaviour of calling animals in social contexts is subdued and 'sleep-like'[1–3].

22-kHz calls in social situations follow interaction between two animals; calls by one animal seem to help pacify the other[1–3]. Since 'spontaneous' calls are not part of any such interaction, their function is not immediately apparent. Nevertheless, it is unlikely that these calls are non-functional because they are so common, because they do not occur randomly, and because they are continually produced even though they could endanger the caller in natural conditions. Many predators are probably sensitive to these calls[9], which are generally quite intense; post-ejaculatory calls can be as intense as 80 dB SPL[2]. If calls promote inactivity in conspecifics regardless of the context, their emission during inactivity could synchronise the behaviour of animals within a colony. Synchrony in the onset and ending of activity in rat colonies has often been observed, and Calhoun suggested that calls during activity may be involved. The present results suggest that calls during inactivity may be responsible. It is also interesting to speculate whether calls by lactating females play any part in forming an association in the pups between the sounds and an inactive or relaxed state.

Bell has suggested that 22-kHz calls indicate a state of decreased "arousal" and may produce a similar state in other rats[10]. The present interpretation of 'spontaneous' 22-kHz calls is consistent with both suggestions. Bell further suggests that current hypotheses about functions of rodent ultrasounds may be unnecessarily complicated because they are based on information about the structure and behavioural context of the calls. He advocates research into the physiological state of the calling animal and into the effects of calls on conspecifics. My results indicate that this approach will be necessary in future studies of 22-kHz calls in rats.

I thank Professor J. D. Pye for advice, laboratory facilities and comments on the manuscript, and Drs G. D. Sales and J. C. Smith for comments on the manuscript.

Specific alterations in phosphorylation of cytosol proteins from differentiating neuroblastoma cells grown in culture

THERE have been a number of reports[1–10] which indicate that an experimentally induced elevation in the intracellular level of adenosine-3′,5′-monophosphate (cyclic AMP) in mouse neuroblastoma cells induces and increases the expression of many differentiated functions that are characteristic of the mature neurone. The irreversibility of cyclic AMP-induced "differentiation"[3] was attributed to the increased level of proteins which bind cyclic AMP thereby protecting the newly synthesised cyclic nucleotide from hydrolysis[11,12]. However, the mechanisms by which cyclic AMP initiates the observed morphological[1–3] and biochemical[1–10] alterations remain unclear since the activity of cyclic AMP-dependent protein kinase did not change in differentiated cells[13]. We have investigated the phosphorylation of specific proteins in control and 'differentiated' neuroblastoma cells. We report here that the cyclic AMP-dependent phosphorylation of a specific protein in the cytosol of 'differentiated' cells increased while the cyclic AMP-independent phosphorylation of another protein in this cell fraction decreased. These selective alterations may represent intermediate steps in a series of events which ultimately lead to the expression of differentiated functions.

Cells of the previously defined[3] clone NBP$_2$ were cultured and maintained as previously described[1]. Differentiation was induced by treating the cells for 3 days with 4-(3-butoxy-4-methoxybenzyl)-2-imidazolidinone (R020-1724)[11], a rather specific inhibitor of cyclic AMP phosphodiesterase[14,15]. Control and treated cells were homogenised in 0.25 M sucrose containing 0.05 M Tris-HCl buffer (*p*H 7.4), 3 mM $MgCl_2$ and 4 mM 2-mercaptoethanol[11,12]. The cytosol (supernatant of a 9×10^6 g min centrifugation) was diluted in homogenising buffer to contain 2 mg protein ml^{-1} (Lowry method) and stored at the temperature of dry ice until assayed. Endogenous protein phosphorylation was assayed as previously described[16]. Each of the samples studied was also tested for ^{3}H-cyclic AMP binding. Binding was found to be two-fold higher in 'differentiated' cells compared to the controls, as previously reported[11,12].

The cytosol of neuroblastoma cells revealed the presence of over 40 protein bands after the proteins of this fraction were electrophoresed in SDS gels. No differences in staining patterns were observed between samples obtained from control cells, cells that had been treated with RO20-1724, and cytosol fractions treated with the drug *in vitro* (Fig. 1). Incubation with ATP before electrophoresis also did not affect the patterns. Protein bands that incorporated ^{32}P-phosphate upon incubation were designated according to their apparent molecular weight (Fig. 1, autoradiogram). Five of these protein components (bands 55, 59, 72, 88, and 97) incorporated considerably more ^{32}P-phosphate than the other phosphorylated bands (Figs 1 and 2). Of these five major bands, the phosphorylation of one band (band 97) was not affected by exogenously added cyclic AMP. Phosphorylation of this band decreased approximately two-fold after differentiation (Table 1). The phosphorylation of the other major bands (bands 55, 59, 72 and 88) was stimulated by cyclic AMP. Addition of cyclic AMP (5 μM) stimulated phosphorylation 128–208% depending on the protein band; the highest stimulation was noted at band 59. Compared with control cells, these four major bands of the differentiated cells showed a marked increase in phosphorylation which varied from 1.2- to 2-fold. The greatest increase occurred in band 59 (Table 1). The percentage stimulation of phosphorylation caused by the addition of exogenous cyclic AMP to samples from differentiated cells was only slightly higher than in control cells. The concentration of cyclic AMP required for half-maximal stimulation (about 0.1 μM) was found to be the same in both treated and untreated cells.

In order to test whether residual drug levels in 'differentiated' cells were responsible for the changes in endogenous phosphorylative activity observed, the cytosol

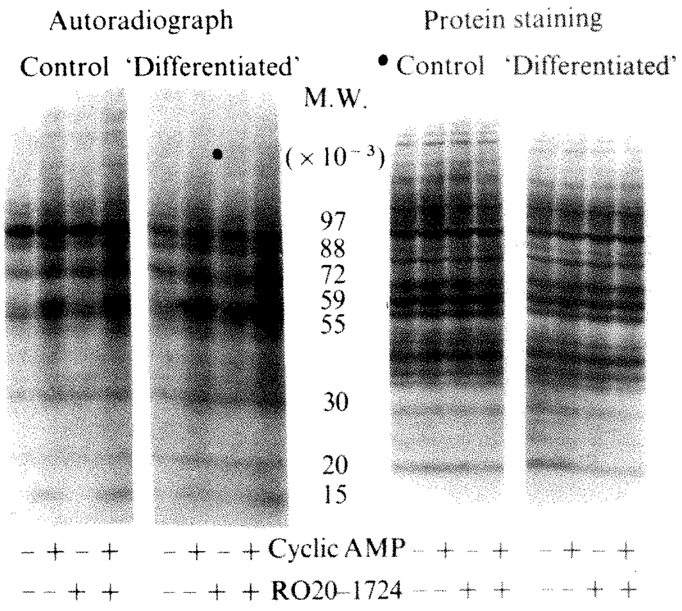

Fig. 1 Identification of endogenously phosphorylated proteins in the cytosol of control and 'differentiated' neuroblastoma cells. Standard assays of endogenous phosphorylation[20] were conducted by preincubating aliquots from the cytosol for 5 min at 30 °C. The reaction was initiated by the addition of γ-^{32}P-ATP (ICN, Irvine, California; diluted with non-radioactive Tris-ATP, Sigma, to a specific activity of 1 to 6×10^7 c.p.m. $nmol^{-1}$) with or without cyclic AMP. The reaction mixture in a final volume of 0.06 ml contained 0.66 mg protein per ml, 50 mM sodium acetate buffer (*p*H 6.5), 10 mM magnesium acetate and 3 µM ATP. After 1 min incubation at 30 °C the reaction was stopped by the addition of sodium dodecyl sulphate (SDS) solution to a final concentration of 3% SDS containing 5 mM Tris-acetate (*p*H 8.0), 1 mM EDTA, 2% 2-mercaptoethanol, 6% sucrose and 0.01% bromophenol blue which served as tracking dye. The solubilised reaction products were heated in boiling water for 2 min. Aliquots (20 µg protein) were applied to 7–14% linear gradients of polyacrylamide gels that had been polymerised in the Hoffer (California) SE-500-1.5 slab gel electrophoresis unit, and electrophoresed using SDS-discontinuous buffer system and the Ortex 4100 pulsed constant power supply. The gels were subsequently stained with Coomassie-brilliant blue-R, dried in the Hoffer SE-540 gel drier and autoradiographed by placing them in close contact with Kodak-X-Omat X-ray film. Under the electrophoretic conditions used, inorganic phosphate, ATP and lipid bound phosphate migrated more rapidly than the phosphoproteins and did not interfere with their separation. Molecular weight estimations were obtained by electrophoresis of marker proteins on the same gel slabs. The specific activity of γ-^{32}P-ATP was 3.6×10^7 c.p.m. $nmol^{-1}$ and autoradiographic exposure time was 70 h. (–) And (+) respectively refer to the addition of water or 5 µM cyclic AMP with the initiating labelled ATP. (–) and (+) also refer to the inclusion of 2 µg RO20–1724 per 60 µl (+) or solvent (–) during a 20-min preincubation period.

Table 1 Endogenous phosphorylation of five protein components in the cytosols of control and 'differentiated' neuroblastoma cells

	^{32}P-phosphate incorporated (arbitrary units)

R020-1724 was used to induce differentiation[11,12]. Cytosol (100,000*g* supernatant) was prepared and used in the assay of endogenous phosphorylation as described in legend to Fig. 1. Incorporation of ^{32}P-phosphate was determined by analysis of densitometric scans of the autoradiograms (Fig. 2) according to the recommendations of Ueda *et al.*[17]. The results were expressed in arbitrary density units. The results of quantitation by this method were found to be highly correlated (+0.87) with quantitation achieved by scintillation counting of corresponding gel slices[20]. Each value in this table represents the mean ± s.e.m. obtained from three separate preparations which were assayed using γ-^{32}P-ATP with a specific activity of 3.6×10^7 c.p.m. $nmol^{-1}$ in the presence or absence of 5 µM cyclic AMP. Two additional preparations were assayed with ATP of higher specific activity and gave essentially the same results. The latter were not included in the table in order to avoid undesirable normalisation of the data.

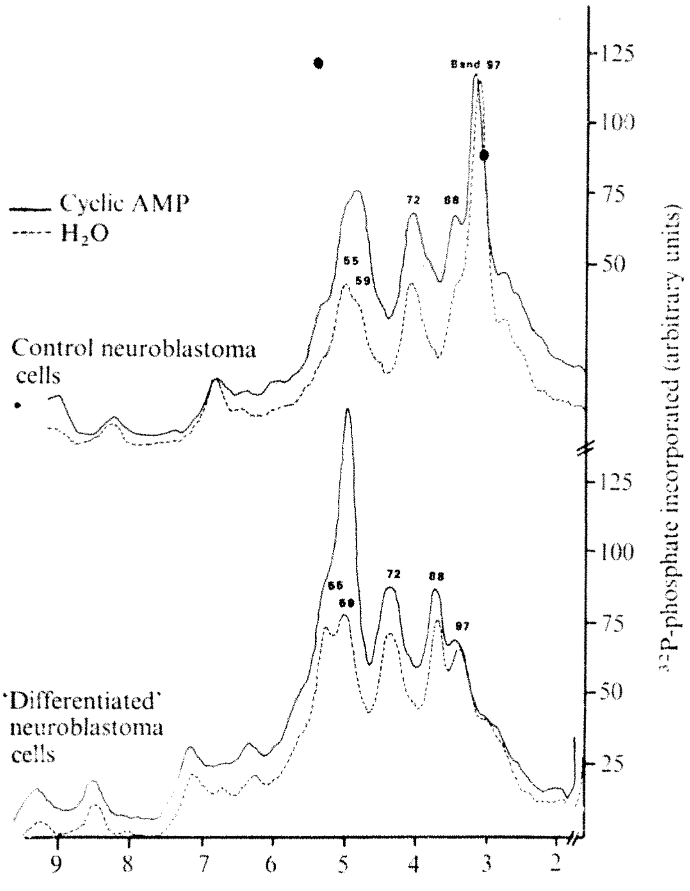

Fig. 2 Densitometric tracings of autoradiograms obtained from polyacrylamide gels after the electrophoretic separation of ^{32}P-phosphate labelled phosphoproteins of control and 'differentiated' cell cytosol. Assays of endogenous phosphorylation in the absence (— — —) or presence (———) of 5 μM cyclic AMP were carried out as described in the legend to Fig. 1. The autoradiograms were then scanned at 649 nm using a Beckman Acta CV spectrophotometer equipped with a linear transport system. Note that the pattern obtained with samples from control cells is characterised by predominance of band 97, while the "differentiated" cells are characterised by the predominance of band 59.

from control and 'differentiated' cells were preincubated for 20 min at 30 °C in the presence of RO20–1724 (2 μg per 60 μl) and the phosphorylative assay was carried out in the presence of the drug (1 μg per 60 μl). This treatment did not alter the phosphorylation patterns (Fig. 1). Thus, the *in vitro* assays of endogenous phosphorylation reflect phosphorylative modifications which had been pharmacologically induced in the intact cells.

The changes in cyclic AMP-dependent and cyclic AMP-independent phosphorylation found in the cytosol of 'differentiated' relative to control cells correlated well with the increase in binding of cyclic AMP by proteins localised in the cytosol of 'differentiated' cells. However, the question of whether the cyclic AMP-binding proteins identified in the cytosol of neuroblastoma cells[11,12] only constitute regulatory subunits of cyclic AMP-dependent protein kinases, or whether some of them can directly affect inductive processes during differentiation, remains to be answered. Preliminary observations in this laboratory have indicated that the phosphorylative alterations that occur in the cytosol were accompanied by an increase in the endogenous phosphorylation of two specific proteins in the crude nuclear fraction. Thus, the observations reported here may be relevant to mechanisms that operate in inductive processes[18].

The changes in phosphorylative activity observed in 'differentiated' cells raises several questions. Do these changes occur after the division rate has slowed down or do they act as biological signals to turn off cell division? Do the phosphorylative changes precede the induction and/or the increase in various differentiated functions[1–10] or do they follow the expression of these functions? Do these phosphorylative changes depend upon the elevation of intracellular levels of cyclic AMP or can other agents, which are known to induce some differentiation[3] without changing the cyclic AMP level, produce similar phosphorylative changes? Are phosphorylative modifications involved in the differentiation processes that occur during normal brain development? It has been suggested that cyclic AMP, in some way, increases the expression of some genes and suppresses the expression of others during differentiation of neuroblastoma cells[3,10,19]. The present findings, which demonstrate both increases and decreases in the phosphorylation of specific proteins during differentiation, lend support to these concepts. The ability of cyclic AMP to produce phosphorylative changes which persist for a long duration was previously demonstrated[20]. The present study indicates that changes of this nature may have a role in neuronal differentiation.

Regulation of cyclic GMP in cerebellum by a striatal dopaminergic mechanism

THE cerebellum has an important function in the coordination of movement and in the regulation of posture. Neurophysiological studies have established that Purkinje cell activity is stimulated by mossy and climbing fibres, which are two distinct afferent excitatory pathways to the cerebellum[1]. Biochemically, an increase or a decrease in the activity of mossy and climbing fibres together with either an activation or inhibition of gamma aminobutyric acid (GABA) synapses of Golgi, basket and Purkinje cells results in changes of the cyclic 3′,5′-guanosine monophosphate (cyclic GMP) content of the cerebellar cortex[2–5]. Therefore, by measuring cyclic GMP in the cerebellar cortex one might infer whether drugs which influence the planning of motor activity and modify operant behaviour also change the activity of the excitatory cerebellar afferents or the function of the inhibitory intracerebellar neurones which presumably employs GABA as transmitter.

We recently reported[6] that an antagonist (haloperidol) and an agonist (apomorphine) of dopamine receptors[7,8] respectively decrease or increase the cyclic GMP content of cerebellar cortex. These changes in cyclic GMP occur without parallel modification of cerebellar cyclic 3′,5′-adenosine monophosphate (cyclic AMP) content[6]. It is currently believed that the cerebellum is devoid of dopamine receptors[9] and that the dopamine present in this structure functions as a precursor of noradrenaline[10]. Since neither cyclic GMP nor cyclic AMP content change as a result of *in vitro* application of dopamine to cerebellar slices[11] or addition of apomorphine or haloperidol to cerebellar homogenates[6], it seems unlikely that these nucleotides function in cerebellum as second messengers of dopamine receptor activation. Hence we have inferred that haloperidol and apomorphine change the cerebellar cyclic GMP content when given parenterally by interacting with dopamine receptors located in other brain areas. An area of the brain which contains a large functional pool of dopamine receptors is the basal ganglia. Changes of cerebellar cyclic GMP could then occur as a consequence of stimulation or blockade of dopamine receptors located in basal ganglia. We have obtained preliminary evidence for such a hypothesis by comparing the changes in cerebellar cyclic GMP content elicited by intrastriatal, intracerebellar and intraperitoneal injection of different neuroleptics and apomorphine.

As shown in Fig. 1, the intraperitoneal injection of haloperidol, chloropromazine and (+)-butaclamol, three drugs that presumably block dopamine receptor function[7,8], produced a dose-related decrease of the cyclic GMP content of cerebellar cortex: a 30% decrease was obtained with as little as 0.1 μmol per kg of haloperidol, 0.2 μmol of chlorpromazine and 1 μmol of (+)-butaclamol. The figure also shows that (−)-butaclamol, which fails to block dopamine receptors[8], also failed to decrease the cerebellar content of cyclic GMP. As is evident from the data shown in Table 1, haloperidol and (+)-butaclamol decreased the content of cyclic GMP in cerebellar cortex also when they were directly infused into the striatum.

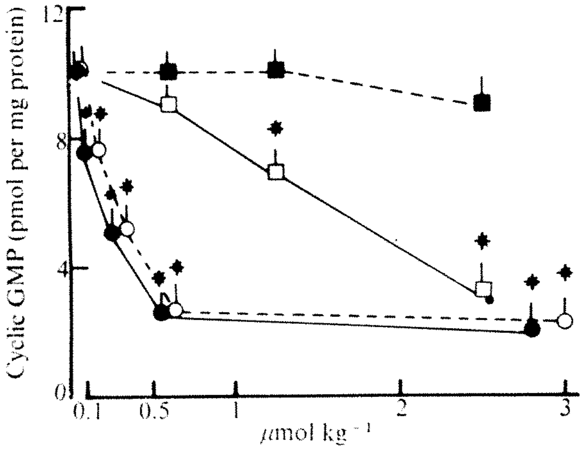

Fig. 1 Decrease in the cyclic GMP content of cerebellar cortex after various doses of haloperidol (●), chloropromazine (○), (+)-butaclamol (□) and (−)-butaclamol (■). Haloperidol, chloropromazine and butaclamol were injected i.p. 30 min before killing the rats. Male Spague–Dawley rats of 130–150 g were killed with a microwave radiation beam focused on the skull[16]. The cyclic GMP content of punches (0.8–1 mg protein) of cerebellar cortex was extracted, purified and assayed as previously reported[16]. Each point is the mean ± s.e.m. of six experiments. *$P < 0.01$ when compared with animals treated with solvent.

Table 1 Effect of intrastriatal and intracerebellar injection of haloperidol and (+) or (−)-butaclamol on cerebellar cortex cyclic GMP content

Drug	µg	Cerebellar cortex cyclic GMP (pmol per mg protein) Intrastriatal injection	Cerebellar cortex cyclic GMP (pmol per mg protein) Intracerebellar injection
Solvent		10.4 ± 4.5	9.8 ± 2.0
Haloperidol	6	4.9 ± 2.3*	10.2 ± 2.6
(+)-Butaclamol	10	5.1 ± 1.8*	10.6 ± 1.6
(−)-Butaclamol	10	9.5 ± 2.1	9.6 ± 2.4

Drugs were injected either directly in striatum (AP = 7.6; L = 2.8; DV = +1.5)[17] or in the cerebellar hemisphere (AP = 3.4; L = 3, DV = −1)[17] through chronically implanted cannulae. The intracerebral injections were made in a volume of 1 µl which was injected at a rate of 1 µl per 2 min. The animals were killed 30 min later.

*$P < 0.05$ when compared to animals treated with solvent. Each point is the mean ± s.e. of four experiments. Rats were killed 30 min after drug injection.

AP = Anterior–Posterior; L = Lateral; DV = Dorsoventral.

A 50% reduction of cerebellar cortex cyclic GMP was obtained by intrastriatal injection of 6 μg of haloperidol or 10 μg of (+)-butaclamol. In contrast, both drugs failed to change cerebellar cyclic GMP content when directly applied to the cerebellum. Moreover, the inactive isomer (−)-butaclamol did not change cerebellar cyclic GMP content after either intrastriatal or intracerebellar injection. Thus the results support the idea that the functional state of striatal dopamine receptors may be responsible for changes of cerebellar cyclic GMP.

In order to determine whether the decrease of cerebellar cyclic GMP content elicited by intraperitoneal injection of antipsychotics was mediated by a blockade of striatal dopamine receptors or by blockade of dopamine receptors located in other brain areas we studied the action of apomorphine injected intrastriatally on the cyclic GMP content of cerebellar cortex. As shown in Table 2, apomorphine (10 μg) injected in both striata increased cerebellar cyclic GMP in control animals and also completely reverted the decrease of cerebellar cyclic GMP in animals pretreated intraperitoneally with haloperidol. Hence, our results demonstrate that the content of cerebellar cyclic GMP can be influenced by activating dopamine receptors in basal ganglia.

The interaction between basal ganglia and cerebellum may occur at various levels. Striatum and cerebellum are

Table 2 Effect of an intrastriatal injection of apomorphine on cerebellar cortex cyclic GMP of rats pretreated with haloperidol

Drug	Cerebellar cortex cyclic GMP (pmol per mg protein) Solvent (1 µl)	Cerebellar cortex cyclic GMP (pmol per mg protein) Apomorphine (10 µg µl^{-1})
Solvent 5 ml kg^{-1} i.p.	9.8 ± 0.36	15.2 ± 0.21*
Haloperidol 0.14 µ mol kg^{-1} i.p.	7.5 ± 0.18*	11.1 ± 0.41†

Apomorphine was injected in both striata through chronically implanted cannulae. Rats were killed 6 and 31 min after apomorphine and haloperidol respectively. Each point is the mean ± s.e. of five experiments.

*$P < 0.001$ when compared with animals treated with solvent.

†$P < 0.02$ when compared with animals treated with 0.14 mol kg^{-1} of haloperidol.

both involved in the coordination and regulation of motor activity and operant behaviour. Both cerebellum and basal ganglia receive a substantial somatosensory input from the cortex, they filter this information and project their modulatory influence back to the cortex through a multisynaptic pathway by way of the ventrolateral talamic nuclei[12,13]. It has been proposed that cerebellum and basal ganglia act in parallel to set up patterns of thalamus cortical output which is necessary for the appropriate activation of cortico-spinal motor neurones[12]. Moreover, neurophysiological data indicate a direct link between basal ganglia and cerebellum suggesting that changes in the activity of striatal neurones can produce parallel changes in the neurones of the cerebellar cortex[14,15]. It is therefore tempting to suggest that the measurement of cerebellar cyclic GMP may be a sensitive biochemical index of the impairment of striatal function elicited by antipsychotics. These results may also be interpreted as preliminary evidence for a cerebellar role in some of the actions of neuroleptic drugs.

Excitatory action of TRH on spinal motoneurones

The recent isolation and characterisation of a number of peptide hypothalamic-releasing (and release-inhibiting) hormones led to an unexpected bonus. Many of these peptides have been found to be widely distributed in brain in areas remote from established hypothalamic neuroendrocrine systems. For instance, two thirds of the brain thyrotropin-releasing hormone (TRH) is located outside the hypothalamus[1,2]. This finding suggests that TRH might have some neuroregulatory role in the brain besides its role as a releasing hormone. The marked behavioural effects of central origin produced by TRH support this notion[3–7]. In particular, the finding that TRH can be localised by immunohistochemical techniques to nerve fibres in a variety of brain regions[8], that it depresses neuronal activity when applied by microiontophoresis[9–11] and that it has stereoselective, high-affinity binding sites in brain[12] suggests that TRH may be a neurotransmitter. There is little evidence, however, on the transmembrane effects and mechanism of action of TRH or other peptides on central neurones.

Spinal motoneurones in the rat receive a moderate density of nerve fibres which are immunoreactive for TRH[8]. This finding provides an opportunity to analyse with intracellular recording the effects of TRH on the membrane properties of central neurones. I show here that TRH has a purely excitatory action with a potency similar to that of glutamate when applied to frog motoneurones. The action of TRH also resembles that of glutamate in that it is often accompanied by an increase in conductance of the membrane. It differs, however, from that of glutamate in that the maximum depolarisation rarely surpasses threshold suggesting that TRH provides a background facilitatory action on motoneurones. The structural requirements for this depolarising action parallel those for the release of thyrotropin[13]. Although immunohistochemical localisation studies have not been performed in frogs, particularly high concentrations of TRH are found in extrahypothalamic tissue[1].

Rana pipiens were chilled on ice and the spinal cord removed, hemisected and placed in a sucrose gap chamber. The activity of motoneurones was recorded by placing a filament of the ventral root across the sucrose gap and the potential difference across the gap was monitored with two calomel electrodes. An upward deflection indicated that the bath electrode was negative relative to the root electrode, signifying a depolarisation of the motoneurones. The cord was perfused with an oxygenated (100%) Ringer solution of the following composition: 114 mM NaCl, 2 mM $CaCl_2$, 2 mM KCl and 10 mM Tris buffer, *p*H 7.3. The temperature was maintained at 18 °C. For intracellular recording glass microelectrodes with tip resistance between 15 and 20 MΩ were selected. Motoneurones were identified by antidromic invasion and only those cells with stable membrane potentials of −65 mV or more were selected for study. The responsiveness of the motoneurone pool was continuously monitored with sucrose gap recording during the intracellular studies. Responses were recorded on a chart recorder and also photographed from the oscilloscope screen. TRH was purchased from Beckman Instruments, Peninsula Laboratories, and Calbiochem Laboratory. All samples gave similar results.

Sucrose gap recording revealed the TRH had a depolarising potency comparable to that of glutamate (Fig. 1*a*). Its action differed from that of glutamate in a number of ways. It was of considerably longer duration (Fig. 1*a*), considerably more variable from preparation to preparation, often showed tachyphylaxis, and the peak of the dose response curve was only 3.7 ± 1.4 mV (s.d.), whereas high concentrations of glutamate resulted in depolarisations of **10** to 20 mV. It is possible that the rapid breakdown of the TRH molecule contributes to the small size of the response, although the addition of a peptidase inhibitor, bacitracin[4], (5×10^{-5} M) (Calbiochem) or lowering the temperature did not increase the size of the response. Blockage of synaptic transmission either with magnesium ions (10 mM) or tetrodotoxin (5×10^{-6} M) reduced the size of the TRH response by 10–40%, suggesting that there are both direct and indirect components to the depolarisations. Equimolar concentrations of pyroglutamate, histidine, or prolinamide, the amino acid constituents of the TRH molecule, either had no effect or an inhibitory action, indicating that the depolarisation cannot be explained by the activation of amino acid receptors by one of these amino acids following breakdown of TRH to its constituent amino acids. Furthermore, the 1-methyl-histidine-TRH analogue was devoid of activity, while the 3-methyl-histidine-TRH analogue was approximately 10 times more potent than TRH.

Intracellular recording from motoneurones ($n=43$) confirmed that TRH had a depolarising action and that maximum depolarising concentrations resulted in a low level depolarisation (5.6 mV ± 3.23 s.d., $n=43$) which never

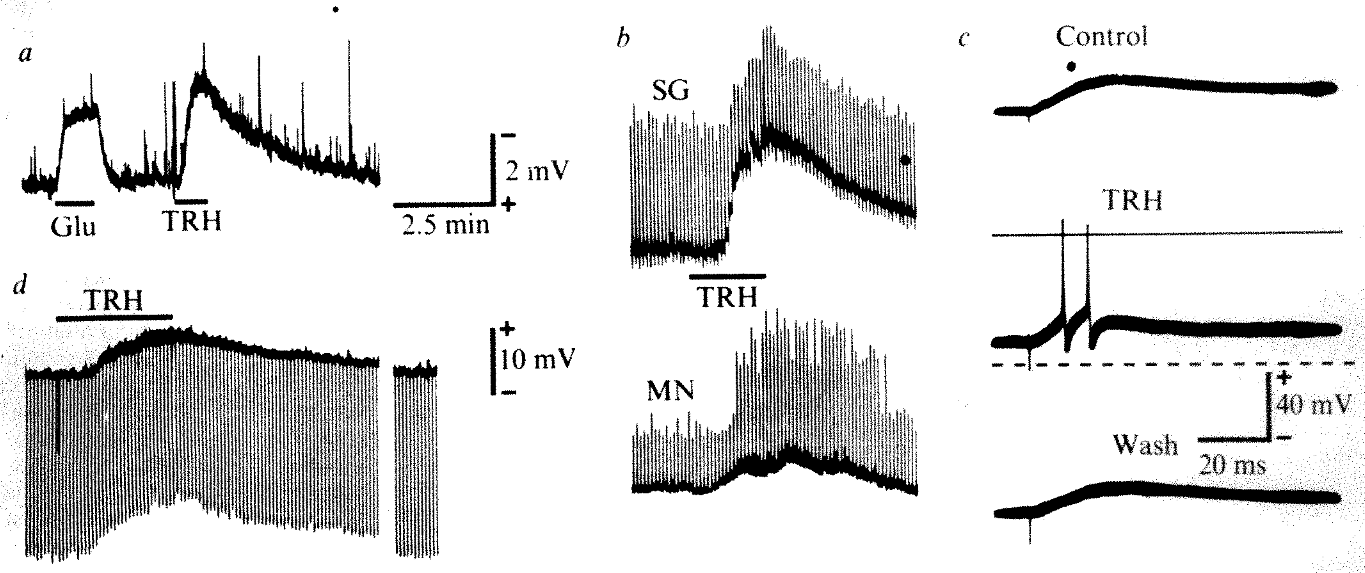

Fig. 1 Depolarising action of TRH on frog motoneurones. *a*, depolarisation of motoneurones to L-glutamate (10^{-4} M) and TRH (10^{-4} M) recorded with sucrose gap from a ventral root. The rapid depolarising deflections result from spontaneous synaptic input to the motoneurones. In *b*, subthreshold e.p.s.p.s which appear as upward deflections reach threshold during TRH depolarisation (5×10^{-4} M). Top trace (SG) is sucrose gap pen record from ventral root and bottom record (MN) is the intracellular response simultaneously recorded from a motoneurone (resting potential, -77 mV). Dorsal root was stimulated every 5.5 s. Spikes during depolarisation in lower record are attenuated in the pen record. *c*, Film records showing e.p.s.p. and spikes from another motoneurone (resting potential, -75 mV). In *d*, constant current hyperpolarising pulses were applied through the microelectrode every 5.5 s which appear as downward deflections (resting membrane potential, -85 mV). The membrane resistance fell from 3.1 MΩ to 2.8 MΩ during TRH. The gap in the record is 5 min. The time calibration in *a* also applies to the other chart records. The voltage calibration in *a* (negativity up) also applies to the sucrose gap record in *b*. The voltage calibration in *d* (negativity down) also applies to the intracellular record in *b*.

reached firing threshold in uninjured cells. This depolarisation did, however, have an excitatory action, raising subthreshold excitatory postsynaptic potentials (e.p.s.p.s) and depolarising current pulses above threshold. This is shown for e.p.s.p.s in Fig. 1*b* (bottom record) and *c*, from two different motoneurones. To analyse the mechanism underlying the depolarisation, membrane resistance was monitored by passing constant current hyperpolarising pulses. In 11 out of 21 motoneurones examined a small decrease in resistance occurred during the depolarisation (Fig. 1*d*). The inability to detect a resistance change in some cells is probably due to the small size of the depolarisation and to limited current carrying capacity of the microelectrodes. The resistance change seen with TRH was of a similar magnitude to that produced by an equivalent depolarisation by glutamate, suggesting that TRH increases conductance to sodium ions.

In summary, the present results indicate that TRH produces in frog motoneurones a long duration depolarisation of small magnitude which is accompanied by an increase in membrane conductance and excitability. Very similar results have been observed with the peptide substance P (refs 15, 16 and unpublished observations). Such actions suggest that TRH and substance P act in a background manner to facilitate transmission through more powerful synaptic pathways subserving reflex activity. The excitatory action of TRH on motoneurones is in contrast to its inhibitory action on supraspinal neurones[8–11] raising the possibility that it may act as an excitatory transmitter on one cell type and as an inhibitory transmitter on another. In this regard the excitatory action described in the present report is perhaps more consistent with the behavioural effects of TRH which are generally of a stimulant nature[3–7], and with its ability to release thyrotropin from the anterior pituitary, the latter being associated with an excitation of anterior pituitary cells[17]. Interestingly the structural requirements for the behavioural effects[18], releasing activity[13], and membrane excitatory actions reported here are all quite similar. The direct neuronal effects of TRH strengthen the concept that TRH may play a neurotransmitter role in addition to and possibly unrelated to its well established neuroendocrine role, although similar receptors are involved in both functions.

Saturation of a retinal cone mechanism

IN discussions of the several differences between the rods and the cones of the human retina it is usually stated that rods saturate and cones do not. When measurements are made of the intensity (ΔI) of an incremental flash that can just be detected on a steady background field of intensity I, the cones normally continue to obey Weber's law ($\Delta I/I$ = constant) at very high intensities when nearly all their pigment has been bleached away; but when only a very small fraction of rhodopsin, the rod pigment, has been bleached the incremental threshold for rods begins to rise more rapidly than is predicted by Weber's law. This saturation of the rod signal can be observed when, by careful choice of wavelengths and by exploitation of the directional selectivity of the cones, the rod response is followed to high intensities in normal observers[1]; or when measurements are made on rod monochromats, whose retinae completely, or almost completely, lack cone receptors[2-4]. Alpern, Rushton and Torii[5] have suggested that it is bleaching that prevents saturation in the cones, for the receptor signal depends on the number of quanta actually absorbed and the latter quantity will tend to a limit as more and more pigment is bleached by steady background fields of increasing intensity. Cone mechanisms do saturate when intense, brief flashes are delivered to the unbleached retina[5,6]. We show here that the blue-sensitive receptors, which are normally thought to be cones, can be saturated by steady fields. In this respect they resemble the rods rather than the red- or green-sensitive cones.

Since the green cone mechanism is almost as sensitive to blue light as is the blue mechanism[7], it was necessary to choose experimental conditions carefully in order to follow the isolated response of the blue mechanism to high intensities. The test flash was violet (435 nm); and was large (1° of visual angle) and long (200 ms) in order to take advantage of the spatial and temporal integrative properties of the blue mechanism[8,9]. It was delivered to the fovea, fixation being guided by an array of four small fixation lights arranged in a diamond. A bright yellow (575-nm) 'auxiliary field'[10], which subtended 6.5°, served to maintain the light adaptation of the long- and middle-wavelength mechanisms; it produced a retinal illuminance of 5.48 log troland (equivalent to 0.17 log erg s^{-1} degree^{-2}) and remained present throughout the experiment. The primary adapting field (445 nm) was of variable intensity and was congruent with the auxiliary field. The arrangement of the stimuli is shown in Fig. 1*d*. The experiment was under computer control and a random double-staircase procedure[11] was used to measure the threshold for detecting the violet test flash at each of an increasing series of intensities of the 445-nm adapting field. Four minutes of light adaptation preceded measurements at each new level of the 445-nm field. Other details of procedure, apparatus and calibration were as described elsewhere[12].

Results are shown in Fig. 1*a* and *b*. The broken line has a slope of 1 and represents Weber's law. Clear evidence of the onset of saturation is seen in the rapidly rising increment-threshold function. Blue–violet fields that cause saturation are not very bright: the increment-threshold function exceeds a slope of 1 when the 445-nm field has a value of ~ 100 trolands, although, of course, the photopic troland is not an appropriate measure of light absorbed by the short-wavelength receptors.

At the highest field intensities the function suddenly flattens, and we suggest that here the green cones have taken over the detection of the violet flashes. To test the latter proposal directly we measured the spectral sensitivity of the eye when it was adapted to the most intense 445-nm field, the auxiliary field still being present: different test wavelengths were used in random order and measurements were always made between 4 and 10 min after the onset of adaptation, during which period the threshold is known to be stable for the observer used (J.D.M.). Measurements were made at two wavelengths in each session and at least 3 h elapsed between sessions. The results (Fig. 1*c*) are well fitted by π_4, Stiles's green-sensitive cone mechanism[7]. They could in principle be fitted by the red mechanism, π_5, but definitely not by π_3, the blue mechanism (which is plotted in Fig. 2*c*).

The reader will ask why saturation of the blue receptors has not previously been recorded, either by Stiles or by the many

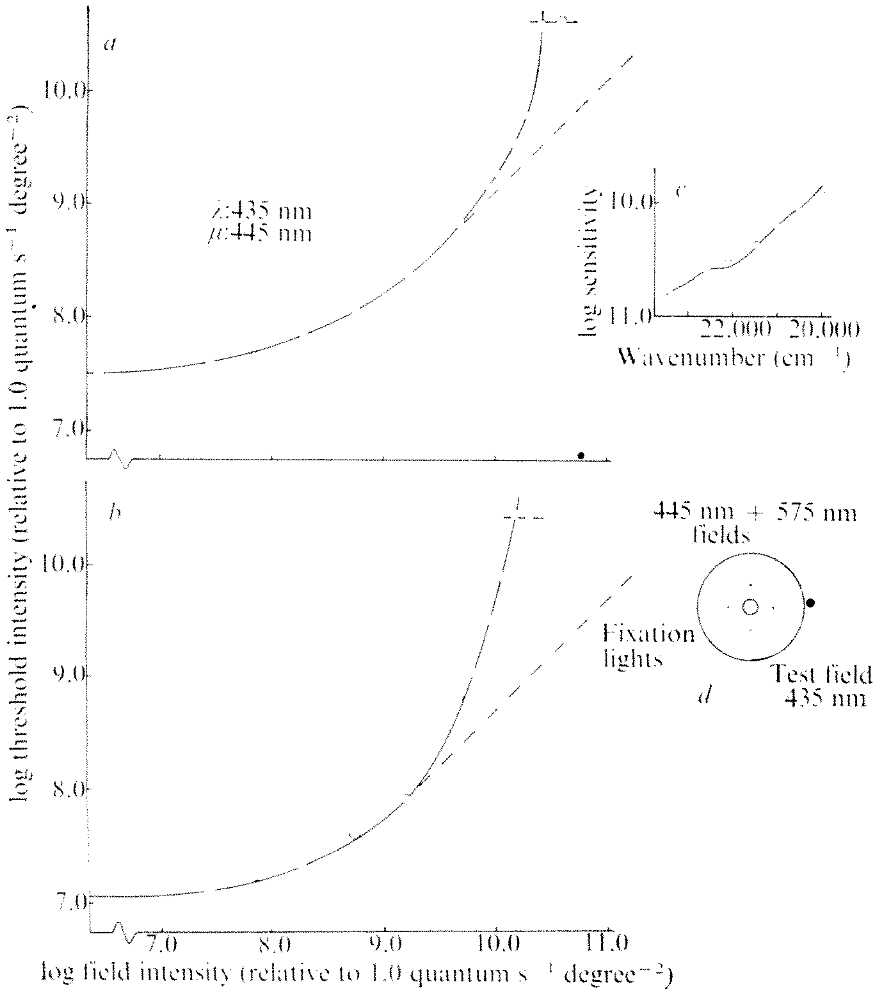

Fig. 1 *a*, *b*, Incremental threshold (Δ*I*) for the 435-nm test flash as a function of the 445-nm primary adapting field. The left-most point represents the threshold on the yellow auxiliary field alone. Observers: J.D.M. (*a*), P.G.P. (*b*). *c*, Spectral sensitivity of the eye after 4 min adaptation to the most intense 445-nm field (10.57 log quanta s^{-1} degree^{-2}). The ordinate is log sensitivity, that is, log reciprocal threshold (relative to 1.0 quantum s^{-1} degree^{-2}). The solid line represents the spectral sensitivity of Stiles's green mechanism, π_4, and has been arbitrarily displaced vertically. *d*, Arrangement of the stimuli.

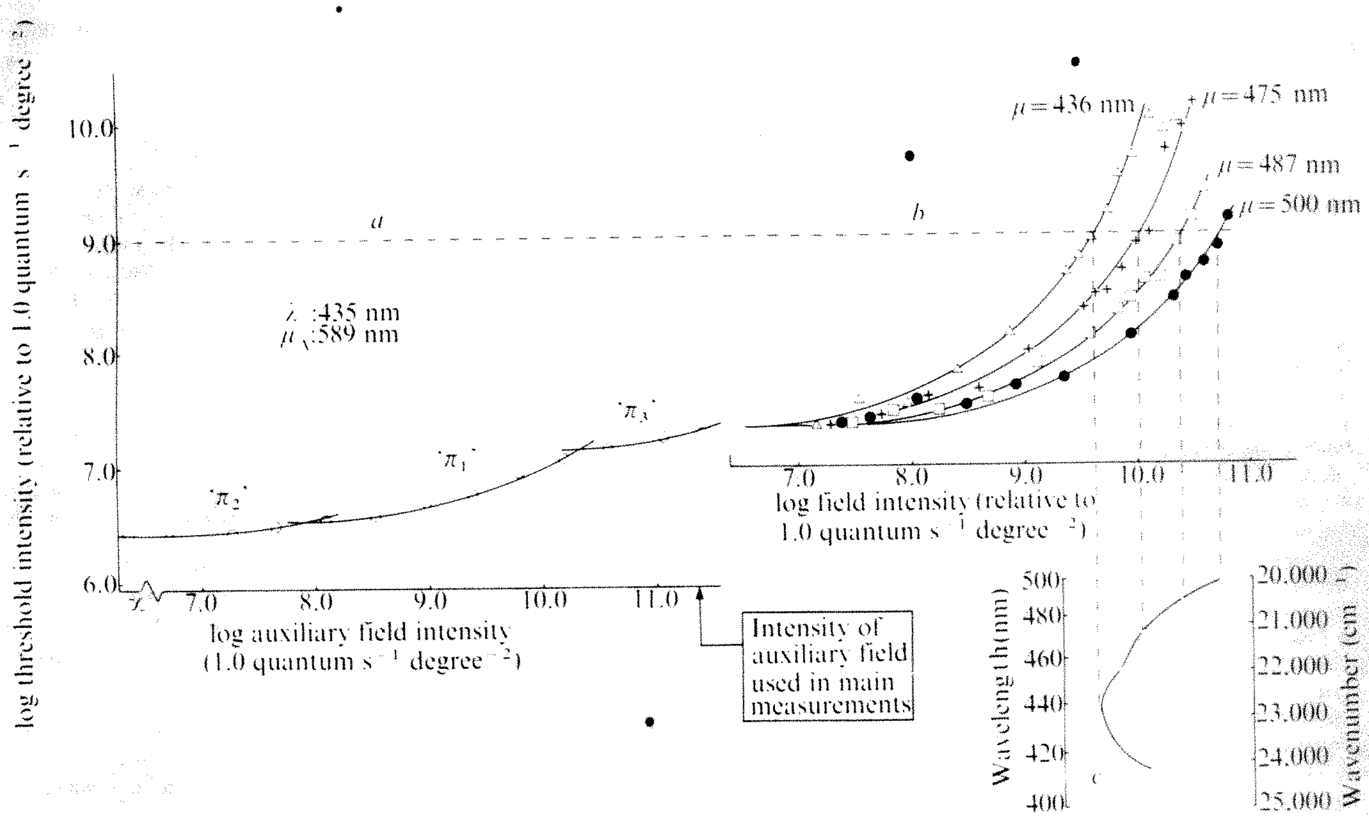

Fig. 2 *a*, Incremental threshold for a 435-nm test flash as a function of the intensity of the orange field alone. The curves fitted to the data points in each case correspond to Stiles's function $\zeta(x)$, taken from Table 7.5, ref. 7; and the relative position on the ordinate of the π_1 and π_2 branches is derived from the tabulated sensitivities of these mechanisms (Table 7.6, ref. 7). The reader should place less weight on the π_2 branch, which has been arbitrarily placed. Observer: J.D.M. *b*, Incremental threshold as a function of the intensity of the main adapting field (μ). The parameter is the wavelength of the main adapting field (μ). The auxiliary field was present throughout. The solid curve is empirical and has been displaced laterally to give the best fit to each set of data. Note that quanta absorbed from the auxiliary field are not represented by the abscissa of this plot. (The theory of the auxiliary field is discussed by Stiles in ref. 10). *c*, Field intensities that produce criterion saturation plotted against wave number. The solid line represents the field sensitivity of Stiles's high-intensity blue mechanism, π_3.

others who have measured increment thresholds using his two-colour procedure. A simple explanation is that many experimenters have not had available the necessary intensities of short wavelength light. But since Stiles is usually cited in support of the claim that cones are never saturated by steady fields, it is interesting and reassuring to note that Fig. 11 of the paper[10] published by Stiles in 1953, which represents data collected in conditions similar to those used here, does show an increment threshold function with a final slope that is greater than 1. Stiles used a 555-nm auxiliary field of −2.15 log erg s⁻¹ degree⁻², which was less intense than that of the present experiment: thus the intrusion of π_4 would occur earlier and would mask the most steeply rising part of the function of Fig. 1*a* and *b*. Norren and Padmos[19] have presented electroretinographic evidence that the dynamic range of the blue mechanism is limited.

What causes Weber's law to fail for the blue receptors? There is good evidence that at lower intensities the blue mechanism is subject to inhibition from a long-wavelength mechanism and that Stiles's three blue mechanisms, π_1, π_2, and π_3, correspond to the same receptors in different states of inhibition (for discussion see refs 12 and 13). Does the saturation seen in Fig. 1 arise directly from quanta absorbed by the short-wavelength receptors or is the blue mechanism being inhibited by a mechanism with a different spectral sensitivity? If the former is the case, we should find the lights of different wavelength that produce a given degree of saturation are lights that from other evidence would be thought to produce equal absorption in the blue receptors; but if the alternative hypothesis were correct, then the results of varying the wavelength of the adapting field ought to reflect the spectral sensitivity of the putative inhibitor. These expectations were the basis for a second experiment, in which the wavelength of the primary field was varied.

The conditions for the second experiment were similar to those of the first, but the wavelength of the auxiliary field (μ_A) was lengthened from 575 to 589 nm, in order better to reveal Stiles's π_3 mechanism, and its brightness was reduced to 5.2 log troland (−0.03 log erg s⁻¹ degree⁻²). The left-hand panel of Fig. 2 shows the effect of the orange auxiliary field alone on detection of the violet test flash. The three shallow branches correspond to Stile's mechanisms π_1, π_2, and π_3. The final level of the orange field (marked with an arrow) was that used as the auxiliary field during the main measurements and it is seen to raise the threshold by about one $\log_{10}$ unit.

Primary adapting fields of varying wavelengths were then added to the orange auxiliary field, a single experimental session being devoted to each wavelength. Results for four adapting wavelengths are shown in Fig. 2*c*; the results for other wavelengths are not shown to avoid congestion on the plot, but they are very similar in form.

Each set of data can be fitted well by a curve of fixed form that obeys Stiles's displacement rule[14], being displaced along the abscissa without vertical shift or other distortion. Figure 2 shows graphically how from these data can be derived the spectral sensitivity of the mechanism underlying saturation. We take as an arbitrary criterion that field intensity at which the slope of the increment-threshold function is 2. (Since the curve is of fixed shape, any criterion will give the same answer.) For each adapting wavelength this value is projected downwards and plotted against wavelength together with the corresponding points for sets of data not shown. The spectral sensitivity function that results (open triangles, Fig. 2*c*) is extremely well fitted by Stiles's curve for π_3, which is taken from ref. 7 (Table 7.6) and which can on several grounds be regarded as a good estimate of the spectral sensitivity of the blue receptors. That the fit is good must follow from the fact that the increment threshold functions of Fig. 2*b* have a fixed shape, for Stiles's measurements of the field sensitivity of π_3 were made in similar conditions but with a lower criterion.

Basic to this derivation is the assumption that Rushton[15] has called the principle of univariance: the output of a receptor depends only on the number, and not on the wavelength, of the quanta caught. As we vary wavelength, all that will change is the proportion of incident quanta that are absorbed. If the data of Fig. 2*b* could be plotted in terms of quanta actually absorbed then all the curves would coincide; but the abscissa is in fact the number of quanta delivered to the cornea and thus each curve is displaced laterally by a distance equal to the log of the ratio of quanta incident to quanta absorbed. It is these displacements that give us the spectral sensitivity of that which causes the saturation.

We conclude that the blue mechanism saturates when the blue-sensitive receptors are themselves absorbing a fixed number of quanta from a field. The present experiment offers no evidence for inhibition.

The saturation of the blue receptors at relatively low intensities may account for several long-standing problems of colour vision. It may, for example, explain why violet lights show a Bezold–Brücke hue shift towards longer wavelengths, coming to appear pale blue as their intensity is increased[16,17].

We have some evidence that if adaptation is maintained at saturating levels for more than 15 min, a recovery of sensitivity occurs: this further anomaly, which recalls physiological findings for rods in the skate[18], is under investigation.

ATP-dependent calcium storage in presynaptic nerve terminals

CALCIUM ions, which enter presynaptic nerve terminals during depolarisation, trigger transmitter release from the terminals of both peripheral[1] and central[2] neurones. The subsequent disposition of the entering Ca is not entirely settled. Although this Ca must eventually be extruded in order for the neurones to return to the steady state, some of it may be temporarily retained and sequestered in intraterminal organelles. We now present evidence for an intraterminal, ATP-dependent Ca storage system which may help to regulate internal ionised Ca concentrations. This latent Ca sequestering system has been revealed by lysis of pinched-off presynaptic nerve terminals ("synaptosomes") in hypotonic media, followed by measurements of ATP-dependent Ca uptake from media containing mitochondrial inhibitors. These observations provide an alternative to the suggestion[3,4] that intraterminal mitochondria may be the primary Ca storage sites.

Synaptosomes were prepared from homogenates of rat brain cerebral cortex by the procedure of Hajós[5]. The synaptosomes (in 30–40 ml of 0.8 M sucrose), were diluted[6] to about 200 ml with an ice-cold buffered physiological salt solution (145 mM NaCl, 5 mM KCl, 1.3 mM $MgCl_2$, 2.4 mM NaH_2PO_4 and 20 mM HEPES [*N*-2-hydroxyethyl piperazine-*N*′-2-ethanesulphonic acid] buffered to *p*H 7.65 at 20 °C with Tris [hydroxymethyl] aminomethane base); the protein concentration, after dilution, was 0.11–0.15 mg ml^{-1}. Aliquots of the saline-diluted suspensions were centrifuged at 15,000*g* for 5 min at 5 °C. The supernatant solutions were discarded, and the synaptosome pellets were resuspended and used for the ^{45}Ca uptake studies described below (see figure legends for details). In each experiment, several representative pellets were assayed for protein by the Lowry method[7].

Following incubation in ^{45}Ca-labelled fluids, aliquots (containing 0.2–0.3 mg protein) of the suspensions were pipetted on to 2.5 cm diameter, 0.3 μm pore diameter Millipore filters (Millipore, Bedford, Massachusetts). The fluid was filtered by suction, and the filters were washed three times with 4 ml aliquots of ice-cold physiological salt solution (see above) containing 1.2 mM $CaCl_2$. The ^{45}Ca content of the material on the filters, and of samples of the ^{45}Ca incubation solutions, was determined by standard liquid scintillation spectrometry.

There is considerable evidence that synaptosomes reseal and exhibit functional properties similar to those of intact nerve terminals when incubated in physiological salines[2-8].

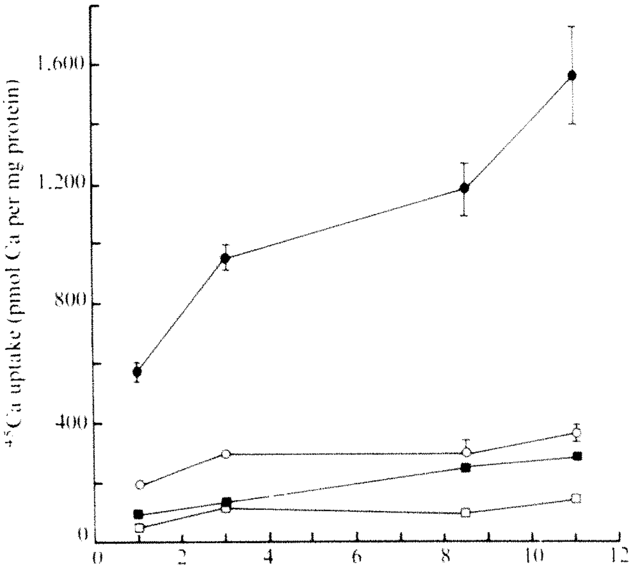

Fig. 1 Time course of ^{45}Ca uptake by intact and disrupted synaptosomes in the presence and absence of ATP. The "intact" synaptosomes (□, ■) were incubated in 2 ml of the standard physiological salt solution (see text) containing 10 μM $CaCl_2$ labelled with ^{45}Ca; the solution also contained 0.1 mM DNP, 0.1 mM Na azide and 0.7 μg ml^{-1} oligomycin. Other ('disrupted') synaptosomes (, ●) were resuspended and incubated in 2 ml of a solution similar in composition except for the omission of all the NaCl; the sudden exposure to the markedly hypotonic media presumably induced lysis[8]. When 2 mM ATP was present (●, ■), the $MgCl_2$ concentration in the incubation fluid was increased to 3 mM; open symbols refer to tissue incubated in ATP-free solutions. Incubations were carried out at 30 C; the protein concentration in the suspensions was 0.41 mg ml^{-1}. Each symbol represents the mean of three determinations; error bars are shown where the standard errors extend beyond the borders of the symbols.

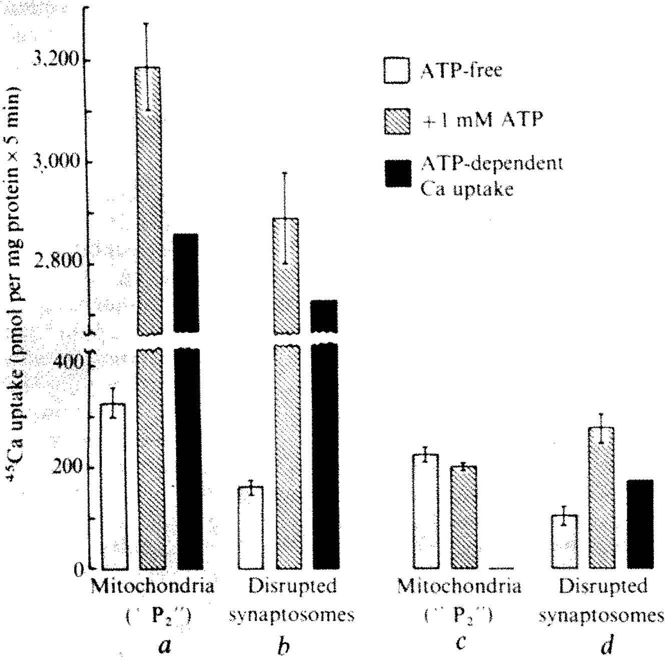

Fig. 2 Comparison of ^{45}Ca uptake by mitochondria and disrupted synaptosomes. The "crude mitochondrial pellet" ("P$_2$", ref. 10) was suspended in about 30 ml of ice-cold 0.32 M sucrose. Half of the suspension was used to prepare a synaptosome-enriched fraction by the method of Hajós[5]. The remainder was immediately diluted with about 100 ml of ice-cold standard physiological saline; isotonic solutions were used in order to avoid lysis of the nerve terminals present in this fraction (see Fig. 1). Aliquots (6 *ml*) were pipetted into centrifuge tubes and the particulate material was pelleted by centrifugation at 15,000*g* for 5 min at 5 °C. The supernatant solutions were discarded, and the pellets (1.39 mg protein) were suspended in 1.0 ml of physiological saline with all the NaCl replaced by KCl (*a*,*c*); the solution pipetted into some tubes (*a*, *c*) also contained DNP, NaN$_3$ and oligomycin (to give final concentrations of 0.1 mM, 0.1 mM and 0.7 μg ml^{-1}, respectively). After 1 min of incubation at 30 °C, 1 ml of similar K-rich saline containing 10 μM Ca labelled with ^{45}Ca was added; the solution added to some tubes (see graph) also contained ATP (final concentration = 1 mM). Following a 5-min incubation at 30 °C, aliquots of the suspensions were filtered and treated as described in the text. The synaptosomes obtained by gradient centrifugation[5] of the sucrose-suspended "P$_2$", were diluted with saline and centrifuged (see text). The pellets (0.93 mg protein) were suspended in 1 ml of "lysis solution" (standard physiological saline with all the NaCl omitted) (*b*, *d*); the solution used to suspend some of the pellets also contained the three mitochondrial poisons (*d*). After 1 min of incubation at 30 °C, 1 ml of buffered saline containing 290 mM KCl (and no NaCl) was added to each suspension; this solution contained 10 μM CaCl$_2$ labelled with ^{45}Ca and, where appropriate (see graph) ATP (final concentration = 1 mM). Following a 5-min incubation at 30 °C aliquots of the suspensions were filtered and treated as described in the text. Each bar represents the mean of three determinations; error bars indicate ± s.e.m.

Figure 1 shows that when the external Ca concentration is about 10 μM, ATP has little effect on Ca uptake by intact synaptosomes incubated in the physiological salt solution with an osmolarity of about 320 mosM. If, however, the synaptosomes are disrupted by exposure to markedly hypotonic media[5], a new Ca uptake process appears—one which is greatly enhanced by ATP (Fig. 1). The fact that it is observed in lysed, but not in "intact", preparations suggests that the uptake mechanism is associated with intraterminal organelles. Following lysis, re-introduction of a 320 mosM solution does not abolish the ATP-stimulated Ca uptake (see Figs 2–4). This ability to withstand large changes in osmotic pressure is reminiscent of fragmented sarcoplasmic reticulum, which can be isolated in 30 mM KHCO$_3$ and then returned to an approximately 300 mosM solution for Ca uptake studies[9].

Participation of mitochondria in this ATP-stimulated Ca uptake can be ruled out, because all incubation solutions contained 0.1 mM 2,4-dinitrophenol (DNP) and 0.1 mM sodium azide (two mitochondrial uncouplers), and 0.7 μg ml^{-1} oligomycin (an inhibitor of mitochondrial ATP-promoted Ca uptake); this combination of poisons blocked virtually all (99±1%; $n=4$) of the Ca uptake in control

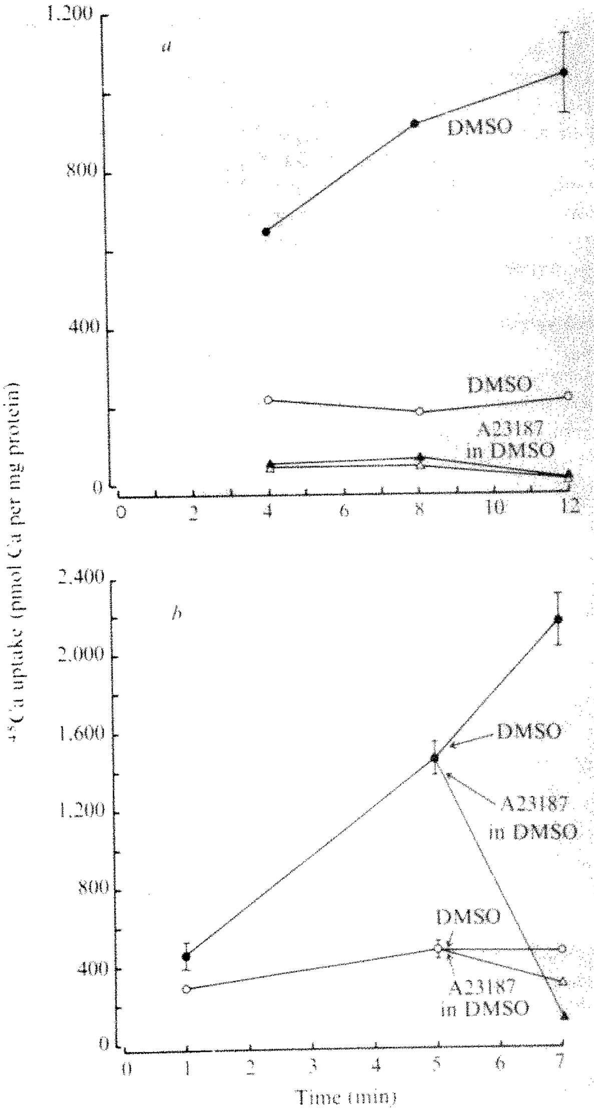

Fig. 3 Effect of ionophore, A23187, on ^{45}Ca uptake by disrupted synaptosomes. Data in *a* and *b* are from different synaptosome preparations. In both experiments, the synaptosomes were disrupted by pre-incubating them for 1 min in 1 ml of standard physiological salt solution with the NaCl omitted. Incubation fluid (1 ml) was then added to provide a (final) composition similar to that of the standard solution, but with all of the NaCl (145 mM) replaced by KCl. In addition, the incubation fluid contained sufficient ^{45}Ca-labelled CaCl$_2$ to give a final concentration of 10 μM in Ca; when 2 mM ATP was present (●, ▲), the MgCl$_2$ concentration was increased to 3 mM. All lysis and incubation fluids contained 0.1 mM DNP, 0.1 mM Na azide and 0.7 μg ml^{-1} oligomycin. All incubations were carried out at 30 °C. Each symbol represents the mean of three determinations; error bars are shown where the standard errors ranged beyond the borders of the symbols. *a*, ^{45}Ca-labelled incubation fluids containing dimethylsulphoxide (DMSO; final concentration = 4.2 μl ml^{-1}) without (○, ●) or with A23187 (△, ▲; final concentration = 10 μM), were added at zero time; the DMSO was used as a solvent for the ionophore stock solution. The protein concentration in the suspensions was 0.51 mg ml^{-1}. *b*, The ^{45}Ca-containing solutions were added at zero time. As indicated on the graph, DMSO (final concentration = 2.5 μl ml^{-1}), without or with A23187 (final concentration = 10 μM), was added immediately after the 5 min samples were drawn. The protein concentration in the suspensions was 0.49 mg ml^{-1}.

experiments on rat liver and rat brain mitochondria. Figure 2 shows data from a representative experiment in which we directly compared Ca uptake by disrupted synaptosomes and by brain mitochondria (crude mitochondrial fraction "P_2" of Gray and Whittaker[10]). Note that, in the presence of the mitochondrial poisons, ATP significantly increased Ca uptake by the disrupted synaptosomes (Fig. 2*d*) but had no effect on Ca uptake by the P_2 fraction (Fig. 2*c*).

Several observations indicate that the ATP stimulates Ca uptake rather than superficial (surface) binding: (1) The extra ^{45}Ca on the filters is not displaced by the non-radioactive Ca (1.2 mM) in the wash solutions (all experiments). (2) There is no stimulation of Ca uptake by ATP, even after 7 min of incubation, if the incubation is carried out at 3 °C rather than at 30 °C (data not shown). (3) The divalent ion-specific ionophore, A23187, prevents the ATP stimulation of Ca uptake (Fig. 3*a*) and releases previously accumulated Ca (Fig. 3*b*). These data are consistent with the hypothesis that ATP induces "uphill" (that is, against an electrochemical gradient) transport of Ca into vesicular compartments[11]. (4) The ATP-stimulated Ca uptake at long incubation times is enhanced when oxalate is present in the incubation medium (Fig. 4). If oxalate is passively distributed across the membranes of the Ca-accumulating particles, as appears to be the case in fragmented sarcoplasmic reticulum[12], the data in Fig. 4 imply that ATP promotes net transport of Ca into the vesicles so that the intravesicular Ca concentration rises and the calcium oxalate solubility product is exceeded. Atomic absorption measurements of total Ca (unpublished) indicate that ATP (in the presence of mitochondrial poisons) promotes net Ca accumulation by the particulate material in the disrupted synaptosome preparations; in the presence of ATP, oxalate increases the net uptake. (5) The effect of ATP on Ca uptake is greatly reduced in the absence of Mg (data not shown), perhaps indicating that a Mg-dependent ATPase may be involved in Ca sequestration[9,13].

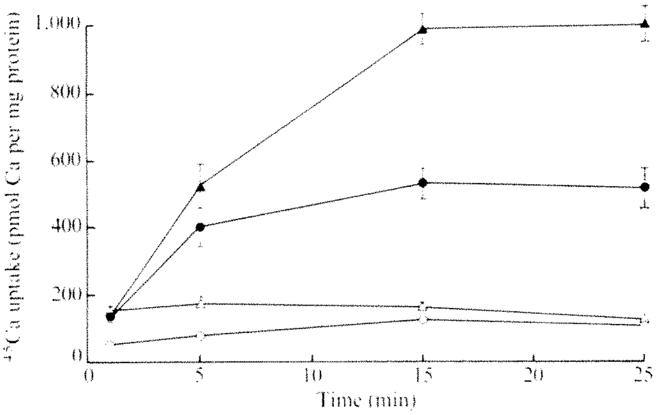

Fig. 4 Effect of oxalate on the time course of ^{45}Ca uptake by disrupted synaptosomes. Synaptosomes were suspended in 1.0 ml of lysis fluid (standard salt solution with NaCl omitted); after 1 min (time zero on the graph) ^{45}Ca-containing solutions (1.0 ml) were added to give a final Ca concentration of 5 μM. The final composition of the incubation solutions was similar to the standard salt solution except that all of the NaCl was replaced either by 145 mM KCl (oxalate-free solutions; , ●) or by 5 mM K oxalate plus 137.5 mM KCl (, ▲); all solutions contained 0.1 mM DNP, 0.1 mM Na azide and 0.7 μg ml^{-1} oligomycin. When 2 mM ATP was present (●, ▲), the $MgCl_2$ concentration was raised to 3 mM. Incubations were carried out at 30 °C; the protein concentration in the suspensions was 0.49 mg ml^{-1}. Each symbol is the mean of three determinations; error bars are shown where the standard errors range beyond the borders of the symbols.

In summary, these experiments suggest that there are vesicular bodies, other than mitochondria, localised within presynaptic nerve terminals, which can accumulate Ca in the presence of ATP and Mg. The properties of this transport system resemble those of fragmented sarcoplasmic reticulum[9,11–14]. Similar non-mitochondrial ATP-dependent Ca sequestration has also been observed in whole brain microsomes[15,16]; however this activity could not be assigned to the synaptic region because of the heterogeneity of the preparations.

Preliminary kinetic data indicate that the ATP-dependent Ca uptake by the disrupted synaptosome preparations has a half-saturation for Ca of less than 1 μM; this sequestration mechanism may therefore operate at physiological intracellular Ca concentrations. By comparison, mitochondria apparently have a lower affinity for ionised Ca: in the presence of physiological K and Mg concentrations, half-saturation for Ca uptake by these organelles may be in excess of 10 to 20 μM Ca (ref. 17). Thus, as an alternative to the hypothesis that mitochondria may be the main intraterminal Ca storage sites[2–4], our data are consistent with the idea that the mitochondria may help to buffer intraterminal Ca primarily by supplying ATP to the transport and storage system described above. This system may therefore play an important role in facilitation and post-tetanic potentiation because these phenomena seem to be the consequence of Ca retention by presynaptic nerve terminals[18,19].

Chemical properties of human Ia antigens

THE human major histocompatibility complex encompasses at least four well-defined loci. Those called HLA-A, -B, and -C control the expression of the classical transplantation antigens (ref. 1). The fourth locus, HLA-D, controls determinants which regulate the ability to stimulate in mixed leukocyte cultures (MLR) and seems at least partly to correspond to the I-region of the murine H-2 complex. A great deal of work has been done on the immunogenetics of the HLA-D locus (reviewed in ref. 2) but despite the fact that alloantibodies against HLA-D determinants are available[3,4] the molecular nature of the antigens is largely unknown. Such studies have been hampered by the fact that HLA-D determinants only seem to be expressed on a small proportion of the peripheral blood lymphocytes (the B cells)[4] but Fu *et al.*[5] have reported data which suggest that B-cell-specific alloantigen is expressed on leukaemic cells. We have therefore isolated a cell membrane glycoprotein complex, controlled by the HLA–D locus, from leukaemic cells of a patient with chronic lymphatic leukaemia. The characteristics of the protein complex strongly suggest that it represents the human equivalent of the murine Ia antigens.

Patient P.S. suffering from chronic lymphatic leukaemia was investigated with respect to the HLA phenotype. Routine tissue typing with a panel of well-defined HLA alloantisera established the phenotype pattern to A1, A2, B8, Bw40, Cw3. The phenotypic pattern of the HLA–D locus was assessed with the MLR test with use of a panel of homozygous typing cells[6]. A clearly positive response for Dw3 was obtained but no other HLA–D specificity could unambigously be assigned to the patient. Additional testing with HLA–D alloantiserum-induced cytotoxicity[7] on the leukaemic cells strongly suggested that the HLA–D phenotype was Dw3 and Dw4.

An alloantiserum obtained from a multiparous woman strongly inhibited the MLR response when the stimulating cells were of the Dw3 phenotype. No effect of the antiserum was noted when lymphocytes of a Dw3 homozygous donor were used as the responder cells and the stimulator cells were of another HLA–D type. The antiserum was as effective in impeding the MLR response even after absorption on platelets of the relevant HLA type, but after absorption, the antiserum was only cytotoxic for B lymphocytes of the Dw3 donor origin. Another alloantiserum which blocked the MLR response stimulated by cells expressing Dw4, was rendered specific for the HLA–D locus determinants by the same procedure.

Leukocytes of patient P.S. were obtained by leukocytopheresis and the lymphocytes were isolated by Ficoll–Isopaque gradient centrifugation[8]. Cell-surface proteins of the isolated cells were labelled by lactoperoxidase-catalysed iodination and Triton X-100-solubilised molecules reactive with the alloantisera directed against Dw3 and Dw4 determinants were precipitated and analysed by SDS-polyacrylamide gel electrophoresis according to a procedure detailed elsewhere[9] (Fig. 1). It is evident that both antisera precipitated two types of polypeptide chains with apparent molecular weights 28,000 and 34,000. No molecules of the HLA-type, that is with apparent molecular weights 12,000 and 45,000, were observed suggesting that the absorption of the antisera had been successful. The specificity of the antisera was also ascertained by the fact that normal human serum did not react with either of the two types of polypeptide chains (Fig. 1*c*). Moreover, absorption of the alloantiserum against Dw3 determinants on Dw3-expressing homozygous cells completely abolished its reactivity with the two polypeptide chains. On the other hand, absorption of this alloantiserum on Dw4-expressing homozygous B lymphocytes did not diminish its reactivity with the two polypeptide chains from Dw3-expressing cells.

In other experiments leukaemic cells of patient P.S. were cultured in the presence of ^{3}H-leucine and ^{3}H-fucose, respectively[9]. Radiolabelled molecules reactive with alloantisera against Dw3 and Dw4 determinants were isolated and analysed by SDS–polyacrylamide gel electrophoresis. With either of the radioactive labels the two polypeptide chain pattern was evident. Consequently, both polypeptide chains contain carbohydrate moieties.

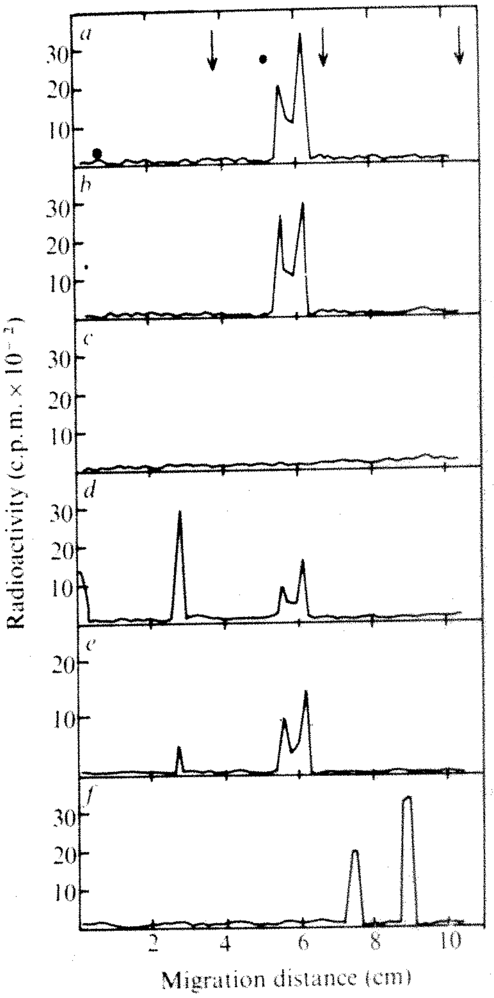

Fig. 1 SDS–polyacrylamide gel electrophoresis under reducing conditions of Triton X-100-solubilised, ^{125}I-labelled membrane antigens reactive with alloantisera directed against HLA-Dw3 (*a*) and HLA-Dw4 (*b*) determinants. No molecules reacted with a normal human serum (*c*). ^{125}I-labelled membrane molecules, crosslinked with TDH, were precipitated by a sandwich procedure using an alloantiserum directed against Dw3 determinants and analysed by SDS–polyacrylamide gel electrophoresis (*d*). The component with the apparent molecular weight 60,000 was extracted from the gel, treated with 15 mM $NaIO_4$ to cleave the crosslinker, and resubjected to SDS–polyacrylamide gel electrophoresis (*e*). The same material as in *a* was analysed by SDS polyacrylamide gel electrophoresis in the absence of reducing agents (*f*). The arrows denote the migration positions (from left to right) of marker heavy and light chains of IgG and the marker dye bromphenol blue. (*a–e*). The markers in (*f*) were immunoglobulin light chains (molecular weight 23,000, migration distance 10·2 cm), ovalbumin (molecular weight 43,000, migration distance 6.0 cm) and bovine serum albumin (molecular weight 68,000, migration distance 3.0 cm).

Since the SDS–polyacrylamide gel electrophoretic analyses were performed in reducing conditions, we looked to see whether the two types of polypeptide chains might be associated by disulphide bonds. In the absence of reduction the two polypeptide chains were separated and, thus, no covalent interaction was apparent (Fig. 1*f*). The two polypeptide chain pattern may result, however, from the existence of non-covalent interactions between the chains in physiological conditions. Alternatively, the alloantisera may react with two independent molecules. To resolve this question Triton X-100-solubilised, ^{125}I-labelled membrane proteins were crosslinked with the cleavable crosslinker tartryl-di(glycylhydrazine) (TDH)[10] and reacted with the alloantiserum against Dw3. Three types of molecules were observed after SDS–polyacrylamide gel electrophoresis (Fig. 1*d*). In addition to the two usually encountered polypeptide chains a new component with the apparent molecular weight 60,000 was evident. The latter was extracted from the gel, the crosslinker cleaved by treatment with $NaIO_4$ (ref. 10), and the material resubjected to SDS–polyacrylamide gel electrophoresis. The result (Fig. 1e) demonstrates that the 60,000-dalton component most probably comprised one polypeptide chain of each type, held together in the denaturing conditions by the crosslinker.

An intriguing observation is that the smaller of the two HLA-D chains always contains more radioactivity than the larger chain regardless of whether external or internal labelling has been used. This result may suggest that the small chain contains more of the labelled residues (leucine, tyrosine, and fucose) than the large chain. Alternatively, the small chain may have a greater turnover than the large chain and consequently may incorporate more of the radioactive precursors. In addition, the small chain could conceivably be more exposed on the membrane surface than the large chain which would account for the results obtained with lactoperoxidase-catalysed iodination (compare ref. 13). Further studies are needed to resolve these possibilities.

Further evidence for a firm non-covalent interaction between the two types of polypeptide chain was obtained from molecular weight determinations in non-denaturing conditions. A large scale isolation of material reactive with the anti-Dw3 alloantiserum was performed. From crude cell membranes of about 200 g of leukaemic cells (expressing the HLA-D specificities Dw3 and Dw4) sodium deoxycholate-solubilised molecules were purified by successive frationation steps involving affinity chromatography on lectin columns and gel chromatography[11]. Of the material in the most highly purified fraction about three-quarters reacted with the HLA-D alloantisera whereas the remainder of the material comprised unrelated molecules. Part of the HLA-D reactive material in this fraction was labelled with ^{125}I and subjected to analytical gel chromatography and sucrose density gradient centrifugation in deoxycholate. The distribution of molecules expressing the allotypic determinants was assessed by indirect immunoprecipitation. The molecules reactive with the alloantisera were eluted earlier than marker HLA molecules and they also sedimented faster than the HLA antigens. The Dw3-expressing molecules were analysed by SDS polyacrylamide gel electrophoresis and the peak fractions always displayed patterns similar to those shown in Fig. 1*a* and *b*. From the values of the Stokes' radius (44 Å) and the sedimentation constant (4.4S) a molecular weight for Dw3 and Dw4-expressing molecules of about 83,000 could be calculated[12]. This molecular weight represents the sum of the weights of the individual polypeptide chains and the bound detergent. Since each one of the two types of polypeptide chains seems to bind an appreciable amount of detergent, but displays much lower values on sedimentation velocity analyses than the intact component (L.S.-T. unpublished observations) it seems likely that the 83,000 dalton complex comprises the two polypeptide chains in a 1 : 1 ratio and about 20,000 daltons of bound detergent.

The present data do not formally exclude the possibility that the glycoprotein complex is composed of two identical polypeptide chains which are very susceptible to proteolysis. No molecules comprising chains of a single type have ever been observed however, and in ^{3}H-leucine labelling experiments the label occurs simultaneously in the two chains. This strongly suggests that the two types of chain are not involved in a precursor–product relationship.

The data reported above suggest that the isolated components may be the human equivalents of the murine Ia antigens (see ref. 13). To investigate this problem in some detail we have raised a rabbit antiserum against the protein complex. Fab fragments of these antisera abolished the lymphocytotoxic action of all HLA-D alloantisera tested and blocked the MLR response when bound to stimulator but not to responder cells in the MLR (L.K., unpublished observations and Ken Welsh, personal communication). These antisera were specific for the HLA-D determinants of normal peripheral blood lymphocytes as revealed by indirect immunoprecipitations and SDS-polyacrylamide gel electrophoresis (Fig. 2), and after solubilised membrane molecules had been reacted with the heteroantisera no molecules remained in the supernatant which bound to the relevant HLA-D alloantisera. One of the antisera (from Ken Welsh) reacted weakly but significantly with ^{3}H-leucine-labelled B10.S splenocyte membrane molecules and, as can be seen in Fig. 2, the polypeptide chain pattern on SDS-polyacrylamide gel electrophoresis is that of typical murine Ia antigens. The heteroantisera did not cross react with HLA antigens derived from the A, B and C loci. Neither did heteroantisera directed against the A, B and C locus gene products[1] react with the glycoprotein complex. This suggests that there is no apparent immunological similarity between the molecules coded for by the D locus and those coded for by the A, B and C loci.

The present data in conjunction with previous reports[15-17] strongly suggest that the HLA-D locus controls the expression of polypeptide chains which are the equivalents of the murine Ia antigens. Like the latter molecules the HLA-D-derived antigens are composed of two types of glycoprotein chains exhibiting immunological cross reactivity with murine Ia antigens which in non-denaturing

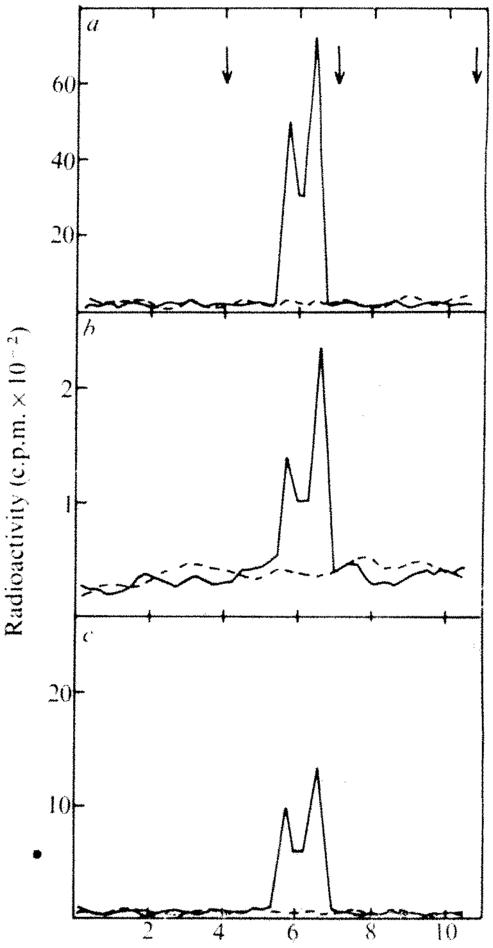

Fig. 2 SDS-polyacrylamide gel electrophoresis of Triton X-100 solubilised, ^{125}I-labelled membrane antigens of lymphocytes from normal peripheral blood reactive with a rabbit antiserum directed against the 83,000-dalton glycoprotein complex (*a*). In (*b*) the same antiserum was reacted with ^{3}H-leucine-labelled B10.S splenocyte macromolecules, and in (*c*) the rabbit antiserum was substituted for an A.TL anti-A.TH serum (anti-Ia^s). In *a*, *b*, and *c* the broken curves represent molecules reactive with normal rabbit serum (*a* and *b*) and normal mouse serum (*c*). The arrows denote the migration positions (from left to right) of marker heavy and light chains of IgG and the marker dye bromphenol blue.

conditions form a stable complex comprising one chain of each type. The protein–protein association seems to involve non-covalent interactions only. Available information does not demonstrate if both polypeptide chains express alloantigenic determinants. It is therefore possible that only one of the chains, as for the HLA antigens[14], is controlled by the HLA region. Studies in progress are aimed at elucidating this question.

We thank Dr Ken Welsh for heteroantiserum. Expert technical assistance was provided by Ms Yvonne Fernstedt. This work was supported by grants from the Swedish Cancer Society, King Gustaf Vs 80-y fund, Åke Wibergs fund, Marcus Borgströms fund, and Harald and Greta Jeanssons fund.

Recognition of a naturally occurring idiotype by autologous T cells

BONE-MARROW-derived (B) lymphocytes belonging to the same clone bear antigen receptors which share a specific marker (idiotype) with antibodies secreted by their progeny[1]. According to the network theory of immunity[2], immunocompetent B cells recognise each other through a network of idiotype anti-idiotype interactions. This theory implies the existence of B and T cells specific for autologous idiotypes. To facilitate detection of such cells it is advantageous to study an immune response of restricted heterogeneity. The immune response of BALB/c mice to phosphorylcholine (PC) is idiotypically homogeneous: the anti-PC antibodies produced bear almost exclusively the idiotype characteristic of the BALB/c PC-binding myeloma protein TEPC-15 (T15) (ref. 3). T15 is a member of a family of PC-binding myeloma proteins of BALB/c origin, which bear distinct idiotypes[4]. Idiotypes representative of these other proteins are not, however, expressed by BALB/c on immunisation with PC. It has recently been reported that helper T cells from BALB/c mice can discriminate among idiotypes expressed on several of these anti-PC myeloma proteins. These authors did not, however, demonstrate helper T cells specific for the T15 idiotype[5]. This failure was attributed to a state of tolerance induced and maintained by the high levels of immunoglobulin bearing the T15 idiotype in conventional BALB/c mice. In this report we demonstrate the existence of T cells reactive to an autologous idiotype and we discuss the possible regulatory role of these T cells in the immune response to PC.

To generate idiotype-specific T cells, conventional and neonatally suppressed BALB/c mice were immunised with T15. Neonatal suppression was accomplished by injecting 0.1 ml of A/J anti-T15 serum at birth as previously described[6]. Mice received a total of 400 μg of protein in a series of four injections over a period of 2 weeks. The first injection was given in complete adjuvant in the foot pads, the second was given in incomplete adjuvant, intraperitoneally (i.p.). The final two injections were given in saline i.p. At least four weeks after the last injection mice were sacrificed and T cells were purified from both spleen and pooled lymph nodes using the method of nylon wool filtration[7]. Dinitrophenyl (DNP)-specific B cells were obtained from BALB/c mice immunised with 100 μg of alum-precipitated DNP conjugated keyhole limpet haemocyanin (DNP_9-KLH) and 10^9 *Bordetella pertussis* organisms. These mice were rested for at least 6 weeks before sacrifice, when their spleen cells were treated with anti-Thy 1.2 serum and complement.

The T15 primed T cell populations were assayed for helper cell activity in a hapten-carrier adoptive transfer system with DNP-primed B cells and DNP-conjugated T15 (DNP_6-T15) as antigen. To demonstrate the specificity of the T15 primed T cells, helper activity was assessed in the same transfer system with DNP-conjugated McPC603 (DNP_6-M603) as antigen. M603 is another myloma protein of BALB/c origin with binding activity for phosphorylcholine and differs from T15 only in its idiotypic specificity[8,9]. Conjugation of either T15 or M603 with DNP did not alter the idiotype determinants which characterise these two myelomas (results not shown). Therefore, these idiotypes should be available as carrier-specific determinants.

DNP-primed B cells were transferred with T15-primed T cells into conventional recipients irradiated with 600 r. Each recipient received 50 μg of aqueous DNP_6-T15 along with the cells. The animals were sacrificed 8 d later and their spleens assayed for indirect anti-DNP plaque-forming cells (PFC) using the Cunningham and Szenberg[10] modification of the haemolytic plaque technique[11]. DNP-conjugated sheep erythrocytes prepared by the method of Inman *et al.*[12] were used as indicator cells.

Table 1 shows that when 3×10^6 DNP-primed B cells were transferred with 10×10^6 T15-primed splenic T cells obtained from suppressed animals, the resulting response was 2,340 indirect anti-DNP PFC per spleen. This response is 16-fold higher than the background response of 142 anti-DNP PFC calculated by summing the responses obtained on transfer of the same cell populations separately. Lymph node T cells from the same T15-primed suppressed animals did not provide any detectable helper activity above background. In addition, neither splenic nor lymph node T cells obtained from T15-primed conventional donors provided as efficient helper activity as splenic T cells obtained from T15-primed suppressed donors; although transfer of either of the non-suppressed T cell populations with DNP-primed B cells did result in an anti-DNP PFC response 6-fold higher than background (Table 1).

Since conventional BALB/c mice have high levels of circulating immunoglobulin (Ig) bearing the T15 idiotype[8], these molecules might compete with DNP_6-T15 and inhibit the helper activity of T15 specific T cells. To optimise the expression of the T15 specific helper cells we used irradiated (600 r) neonatally suppressed[6] BALB/c mice as recipients. These animals contained less than 0.68 μg ml^{-1} of circulating Ig bearing T15 idiotype compared with conventional BALB/c mice which contain between 40–80 μg ml^{-1}.

Table 1 Demonstration of idiotype specific helper T cells

DNP-KLH† primed B	Number of cells transferred (×10⁶)* Suppressed T15 primed‡ spleen T	lymph node T	Conventional T15 primed§ spleen T	lymph node T	Indirect anti-DNP PFC/spleen (×10²)¶
3	—	—	—	—	0.49 (0.30–0.78)
–	10	—	—	—	0.93 (0.66–1.32)
–	—	10	—	—	0.68 (0.30–1.51)
–	—	—	10	—	< 0.4
–	—	—	—	10	< 0.2
3	10	—	—	—	23.4 (13.8–39.8)
3	—	10	—	—	2.9 (2.0–4.3)
3	—	—	10	—	5.4 (3.4–8.6)
3	—	—	—	10	5.0 (2.9–8.9)

*Mixtures of cells were transferred into 600 r irradiated conventional BALB/c mice intravenously. Animals received 50 μg of aqueous DNP$_6$–T15 simultaneously with transferred cells. Animals were sacrificed 8 d after cell transfer.

†DNP-KLH primed spleen was treated with anti-Thy 1.2 serum and complement resulting in a population containing 94% immunoglobulin bearing cells and 2% T cells as assessed by immunofluorescence.

‡Suppressed BALB/c donors were given 0.1 ml of A/J anti-T15 serum intraperitoneally at birth. At 2 months of age suppressed animals were immunised with two injections of 100 μg of TEPC15 per week for 2 weeks. T cells were isolated from spleen and pooled lymph nodes using nylon wool fractionation. The purified splenic T population contained 93% T cells and 1.8% immunoglobulin-bearing cells and the lymph node T population contained 97% T cells and 1.4% immunoglobulin-bearing cells (as assessed by immunofluorescence).

§Conventional BALB/c mice were immunised with TECP15 as the suppressed animals. Splenic T cells and pooled lymph node T cells were purified using nylon wool. The resulting spleen T-cell population contained 90% T cells and 1% immunoglobulin-bearing cells and the lymph node T-cell population contained 95% T cells and 0.6% immunoglobulin-bearing cells (as assessed by immunofluorescence).

¶Geometric mean of the responses of 4 or 5 animals per group. Numbers in parentheses represent one s.e. about the mean. The direct PFC response in all groups was less than 5% of the total response. Indirect PFC were developed using a polyvalent rabbit anti-mouse immunoglobulin serum.

When 2×10^6 or 10×10^6 splenic T cells obtained from T15 primed suppressed mice were transferred along with 3×10^6 DNP primed splenic B cells into suppressed recipients, the resulting anti-DNP PFC responses were 50-fold and 20-fold higher than background, respectively (Table 2). These T cells are specific for the T15 idiotype since transfer of the same cell population with DNP$_6$-M603 as antigen did not result in an anti-DNP response above background (Table 2).

Table 2 Enhanced expression of idiotype specific helper activity in idiotype suppressed recipients*

DNP-KLH‡ primed B	Number of cells transferred† (×10⁶) Suppressed T15 Primed§ Spleen T	Antigen	Indirect anti-DNP PFC per spleen (×10²)¶
3	—	DNP$_6$–T15	3.1 (2.4–4.1)
–	20	DNP$_6$–T15	4.3 (2.6–6.9)
3	20	DNP$_6$–T15	376.0 (301–469)
3	10	DNP$_6$–T15	151.0 (118–193)
3	10	DNP$_6$–M603	8.5 (5.0–14.5)

*All recipients were injected with 0.1 ml of A/J anti-T15 serum intraperitoneally at birth. Recipients were 3 months of age at time of transfer and contained < 0.68 μg ml^{-1} of Ig sharing idiotypic determinants with T15.

†Mixtures of cells were transferred into 600 r irradiated idiotype-suppressed BALB/c mice with 50 μg of aqueous antigen. Animals were sacrificed 8 d after transfer.

‡DNP-KLH primed spleen cells were treated with anti-Thy 1.2 serum and complement resulting in a population containing 93% immunoglobulin bearing cells and 0.7% T cells as assessed by immunofluorescence.

§Spleen T cells were isolated from idiotype-suppressed TEPC15-primed BALB/c mice; see legend to Table 1. The resulting population contained 93% T cells and 1.2% immunoglobulin-bearing cells as assessed by immunofluorescence.

¶Geometric mean of the responses of 3 or 4 animals per group. Numbers in parentheses represent 1 s.e. about the mean. The direct anti-DNP PFC response in all groups was less than 5% of the total response. Indirect PFC were developed using a polyvalent rabbit anti-mouse immunoglobulin serum.

The greater efficiency with which T15-specific helper activity is generated in neonatally suppressed compared with conventional BALB/c mice is perhaps related to the fact that suppressed mice have 100-fold lower concentrations of circulating Ig bearing the T15 idiotype[6]. The high levels of T15 idiotype in conventional BALB/c might partially mask the T15-specific T-cell clones. Consistent with this hypothesis is the finding that T15-specific B cells are also more readily induced in suppressed than conventional BALB/c mice on immunisation with T15 (H.C., A.A. and M.H.J., in preparation). The ability of conventional mice to produce anti-T15 antibodies demonstrates that the T15-specific precursor cells are present but simply not expressed to the same extent as in suppressed mice. Similarly, T15-specific T cells can be induced in conventional BALB/c but not as readily as in suppressed mice.

Splenic T cells isolated from suppressed unprimed BALB/c and transferred along with DNP-primed B cells into suppressed irradiated recipients, failed to give an anti-DNP response significantly above background (data not shown). Thus, if mature T15-specific helper T cells exist in unprimed suppressed BALB/c, there are too few to be detected and/or antigen (T15)-dependent proliferation and maturation of T15-specific precursor T cells might be required for generation of helper activity.

Idiotype-specific T and B cells might play a part in regulation of the immune response to PC. We have recently demonstrated that BALB/c mice can produce antibodies specific for the T15 idiotype. These autologous anti-idiotypic antibodies modulate the idiotypic pattern of the immune response to PC *in situ*, that is, the proportion of antibodies produced which bear the T15 idiotype is reduced compared with normal controls (H.C., A.A. and M.H.J., in preparation). The production of these antibodies is T dependent since 'B mice' (adult thymectomised, lethally irradiated and foetal liver reconstituted) fail to produce anti-T15 antibodies on immunisation with T15 (M.H.J., unpublished).

Although we have shown that idiotype-specific T cells can function as helpers in the production of anti-DNP antibodies, these T cells might also collaborate with B cells of the same specificity in the production of autologous anti-T15 antibodies. Alternatively, analogous to the studies of Eichmann[13], T15-specific T cells could function as suppressor cells and directly regulate the expression of PC-specific B cells expressing receptors bearing the T15 idiotype. We are currently investigating the modes of action of T15-specific T cells in an attempt to define their possible role in regulation of the anti-PC response.

We thank Rosemarie Lang, Heidi Amstutz and John Bews for technical assistance.

Altered expression of human monocyte Fc receptors in malignant disease

SEVERAL kinds of cells involved in immunity can bind antibody or immune complexes through surface receptors which interact with the Fc portion of IgG (Fc receptors). The expression of Fc receptors on mononuclear phagocytes (monocytes/macrophages) can undergo changes in response to various stimuli both *in vitro*[1] and *in vivo*[1-3] and such changes may play a regulatory role in the induction of an immune response and in immunological effector mechanisms. Here I show that the expression of Fc receptors on circulating human monocytes is substantially increased in individuals with solid malignant tumours. This change seems not to be a normal characteristic of infectious or inflammatory diseases of a non-malignant nature.

The experimental group consisted largely of individuals with various bronchogenic carcinomas (squamous cell, oat cell, adenocarcinoma) and included examples of carcinoma of the rectum, pharynx, oesophagus and breast. All were untreated and the majority were without signs of metastatic disease. Control subjects were healthy laboratory workers and were initially age and sex matched with patients until it became evident that significant age and sex differences were not present amongst normal donors. In the study of non-malignant diseases individuals with the most active disease were selected where possible, thus for example, all pulmonary tuberculosis patients had live bacilli in their sputum.

Lymphocytes and monocytes were isolated from 10 ml of heparinised peripheral blood by centrifugation over a Ficoll/triosil gradient. The cells were washed twice, adjusted to approximately 10^6 ml^{-1} in Hank's balanced salt solution (BSS) and 1-ml aliquots of this were placed in each chamber of dual tissue culture slides (Lab-tek products). After incubation at 37 °C for 90 min the glass adherent cells were washed three times with BSS. This procedure resulted in a monolayer consisting of monocytes and a proportion of quite firmly adherent lymphocytes. The former were easily distinguishable from lymphocytes because of the spreading which occurred following monocyte adherence. However, this morphological identification was confirmed by latex particle ingestion[4].

Fc receptor expression was characterised using an assay similar to that described for guinea-pig macrophages[1]. A panel of erythrocytes, bearing increasing amounts of specific antibody, was prepared by incubating a 1% suspension of ox erythrocytes with heat-inactivated rabbit anti-ox antiserum at increasing concentrations in phosphate-buffered saline. After 30 min at 20 °C the cells were washed once and resuspended in BSS at a concentration of 1%. One-millilitre aliquots of sensitised erythrocytes were added to each monolayer and allowed to settle for 1 h at 20 °C. The monolayer were then washed five times with BSS, fixed with 1% glutaraldehyde and stained with buffered Giemsa. Mounted preparations were examined and cells with five or more attached erythrocytes were scored as rosettes. The percentage of rosette-forming monocytes occurring at each increment of erythrocyte sensitisation in a monolayer from a normal donor was compared with that occurring simultaneously in a monolayer from a donor with malignant disease. In the study of non-malignant diseases the comparison between monocytes from

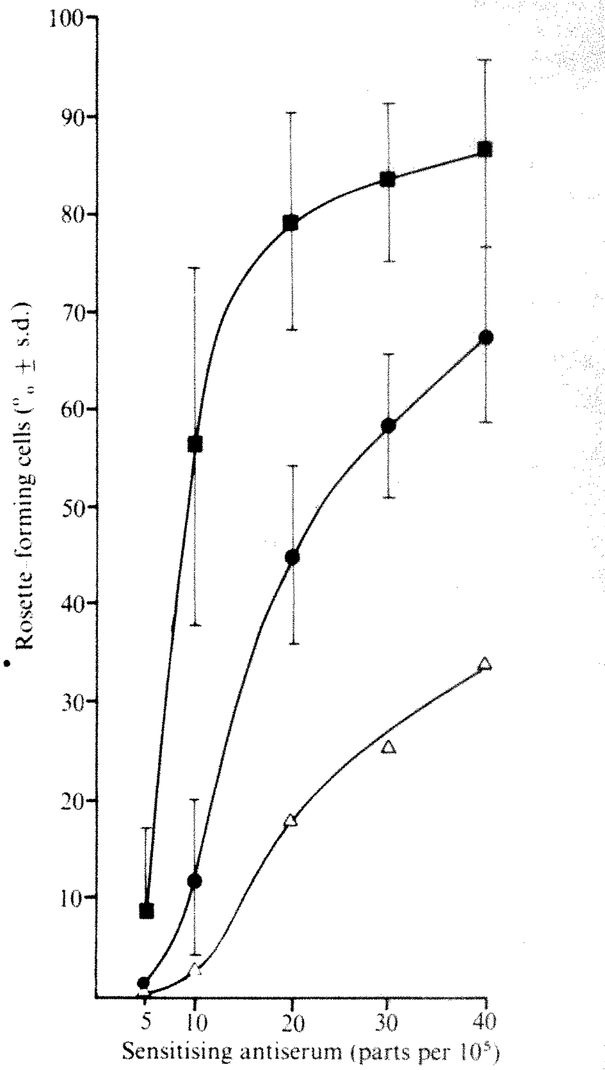

Fig. 1 The percentage of rosette forming monocytes as a function of the degree of erythrocyte sensitisation in fourteen individuals with malignancies (■), in seventeen normal individuals (●), and in one individual with malignant disease (lung cancer) and maturity-onset diabetes (△). Values are expressed as means ± one standard deviation.

Table 1 Occurrence of B lymphocytes, T lymphocytes and T lymphocytes expressing Fc receptors (FcR), as judged by rosette formation, in peripheral blood of individuals with malignant tumours

	Non-T lymphocytes expressing FcR (B lymphocytes and others) % of total	T lymphocytes % of total	T lymphocytes expressing FcR % of total
JC	36.0	64.0	2.5
TJ	35.0	65.0	5.0
MC	35.5	64.5	7.0
RH	39.0	61.0	6.0
SF	35.0	65.0	3.0

Lymphocytes isolated from 10 ml of heparinised peripheral blood on Ficoll/triosil gradients were assayed by the method of Haegert *et al.*[5]. Cells expressing FcR bind ox erythrocytes sensitised at an optimal concentration of antiserum (60 parts per 10^5) while T lymphocytes bind fluorescein-labelled sheep erythrocytes. Any T lymphocytes expressing FcR bind both indicator cells.

patients and from healthy donors was made using those two increments of sensitisation which had been established as optimal for detecting differences in receptor expression. Fc receptor expression by lymphocytes from a group of patients with untreated bronchogenic carcinoma was also characterised by a mixed rosette suspension assay in which T lymphocytes bound fluorescein-labelled sheep erythrocytes and B lymphocytes, and any other cells expressing Fc receptors, bound antibody-sensitised ox erythrocytes[5].

The dose–response curves in Fig. 1 show monocyte rosette formation as a function of the degree of erythrocyte sensitisation. At the second increment the proportion of monocytes binding immune complexes in patients with malignant disease is five times greater than normal. Fourteen of the fifteen patients tested showed a substantial increase in binding at all increments of sensitisation indicating a uniform increase in Fc receptor expresson rather than a change in the proportion of high avidity cells[1]. The one patient who did not exhibit elevated receptor expression showed instead a marked depression in comparison with normal (Fig. 1). This bronchogenic carcinoma patient also had maturity-onset diabetes mellitus and was receiving chlorpropamide at the time of sampling. Insulin inhibits the differentiation of macrophage Fc receptors *in vitro*[6] and a similar effect might explain this *in vivo* observation since higher than normal levels of insulin occur in maturity-onset diabetes[7]. It was not possible to demonstrate any increase in the expression of Fc receptors by T lymphocytes in patients with bronchogenic carcinoma. Very few T cells expressing Fc receptors were observed using the mixed rosette suspension assay of Haegert and associates[5] (Table 1).

The expression of Fc receptors by monocytes from individuals with non-malignant diseases is compared with that of normal donors in Table 2. Each datum is the largest difference observed in percentage rosette formation between a monolayer from the patient and a monolayer from a normal donor assayed simultaneously. Significant differences (greater than 20%) are boxed in for clarity and examples of malignant disease are included for comparison. Significant differences from normal do not seem to occur in the non-malignant diseases tested with the interesting exception of a proportion of patients with active pulmonary tuberculosis (three out of seven). Also, one patient with a surgical wound infection exhibits a significant difference while one patient with a breast lump later found to be malignant does not show significantly altered receptor expression.

Mononuclear phagocytes, in a variety of experimental systems, have been shown to exert a regulatory effect on the function of lymphocytes (reviewed by Nelson[8]). Macrophages seem to release both stimulatory and inhibitory factors which act on lymphocytes[9] while the macrophage surface may adsorb both cooperative[10] and suppressive[11] factors released by lymphocytes. In studies of the apparently complex relationship between macrophage and lymphocyte function one of the more consistent observations has been the suppression of T lymphocyte responses by activated macrophages[8]. In a study particularly pertinent to the present report Berlinger and associates showed that peripheral blood monocytes of patients with malignant tumours exert an inhibitory effect on the blastogenic response of the patients' lymphocytes in mixed

Table 2 Monocyte Fc receptor expression in non-malignant diseases

	No. of cases

Monolayers were assayed using indicator cells sensitised with rabbit anti-ox antiserum at a concentration of 10 and 20 parts per 10^5. Each datum represents the largest difference in percentage rosette formation observed between a monolayer from a patient and from a normal donor assayed simultaneously. Significant differences are marked with an asterisk and examples of malignant disease are included for comparison.

leukocyte cultures[12]. The present study shows that altered expression of monocyte Fc receptors occurs in malignant disease but does not seem to occur readily in a variety of non-malignant diseases. This change in monocyte membrane characteristics may be an appropriate host response, facilitating macrophage-mediated cytotoxicity and the clearance of immune complexes, and tumour progression may occur because of lesions elsewhere in the host's defence system[13]. An alternative possibility is that the change in monocyte surface characteristics, or associated changes, occurring in malignant disease exert a net inhibitory effect on anti-tumour immunity. This might occur locally rather than systemically during the early growth of a tumour. The same macrophage-mediated inhibition of an immune response might also occur in chronic infections such as tuberculosis.

I thank the following for making available samples of their patients' blood: Professor N. M. Bleehen, Dr C. Wiltshire, Professor R. Y. Calne, Mr R. E. Robinson, Dr W. B. Newsom, Dr J. E. Stark, Dr S. Jegarajah, Dr J. Shaw, Dr J. K. Oates, Mr G. Docherty, Dr S. Lachmann, Dr R. H. Champion, Dr D. Rubenstein, Dr A. Smith, Dr P. J. Ciclitira, Dr A. P. Dick. I am supported by the Cancer Research Campaign and by a Beit Memorial Fellowship.

Serological evidence for H–Y antigen in *Sxr*, XX sex-reversed phenotypic males

IT is generally considered that the Y chromosome is necessary for the development of the mammalian testis and the consequent male phenotype. Exceptions occasionally occur in man and other animals, where a male phenotype is associated with an apparently normal female karyotype. In some instances it has been possible to show that such "sex reversal" has an autosomal genetic basis. Although this might imply that the Y chromosome is not a prerequisite of maleness, it has not been excluded that a small male-determining region of the Y may have been translocated to an autosome without producing a recognisable karyotypic change[1] (reviewed in ref. 2). The best studied case of male development with an apparently female karyotype is provided by the *Sxr* mutant in the mouse. This autosomal dominant condition causes both XX and XO mice to develop as males, although germ cells are absent in *Sxr*,XX animals and spermatogenesis is impaired in *Sxr*,XO mice. *Sxr*,XY males have a slightly reduced testis size but are usually fertile. Cytological scrutiny of mitotic and meiotic chromosomes (including chromosome banding) has revealed no evidence for a Y–autosome translocation, although a small translocation undetectable by the methods used cannot be ruled out (reviewed in ref. 2). This situation can now be investigated using serological methods for detecting H–Y (histocompatibility-Y) antigen on the surface of mouse sperm[3] and male epidermal cells[4]. These techniques have provided further evidence that expression of this antigen is governed by a gene (or genes) on the Y chromosome even in the absence of the normal male phenotype[5]. Thus, serological demonstration of H–Y antigen offers a non-karyological criterion for the presence of a translocated portion of the Y in *Sxr*,XX males, because their cells should express H–Y if *Sxr* is a translocation involving the H–Y genetic determinant. We report here that *Sxr*,XX males express H–Y to a degree that may be the same or slightly lower than that of normal males, and that their *Sxr*,XY siblings seem to have near-normal levels of H–Y. The simplest explanation is that male-determining and H–Y-determining portions of the Y chromosome are present in the animals carrying *Sxr*.

The *Sxr* stocks were obtained from Harwell where they are maintained on a mixed C3H/HeH-101/H genetic background with tabby (*Ta*) being used as an X-chromosome

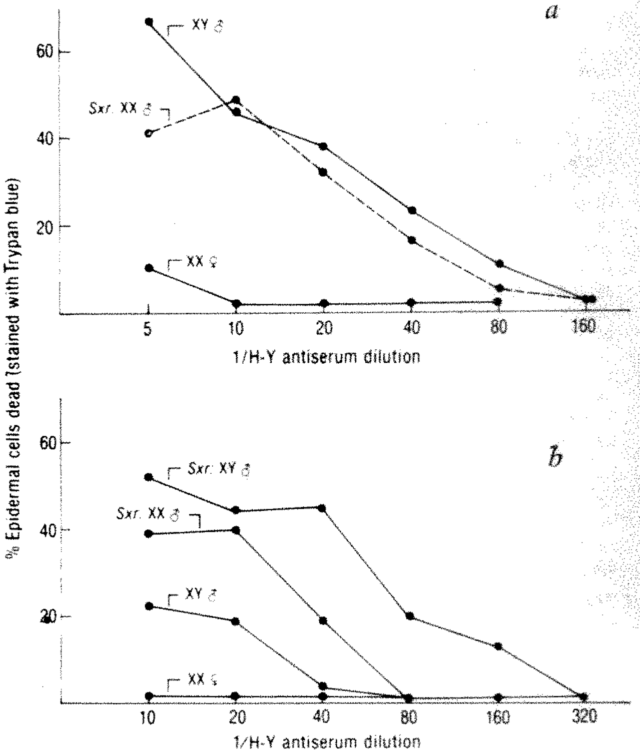

Fig. 1 Demonstration of H–Y antigen on dissociated epidermal cells of *Sxr*,XX and *Sxr*,XY mice by the complement-dependent cytotoxicity assay with anti-H–Y serum. *a*, The data in this figure are from a representative test with two animals in each group. The values shown are mean readings for the pairs of (C3H × 101)F$_1$ outcross stock controls and for the *Sxr*,XX individuals. Antiserum and compelment were the same as indicated in Fig. 1 of ref. 3. Percentage of epidermal cells dead (ordinate) was calculated as indicated in the legend to that figure. *b*, The data in this figure are from one of two sets where *Sxr*,XY males were compared with their sibling XY (non-carrier) males. The two classes of XY male siblings were distinguished on the basis of testis weight. Although this criterion does not provide absolute assurance of genotype, we identified putative *Sxr*,XY animals by testis weight in the extreme low range (0.069 g and 0.078 g) compared with XY males with testis weight in the extreme high range (0.102 g and 0.127 g). The siblings were selected from single litters and were therefore the same age at the time of the test.

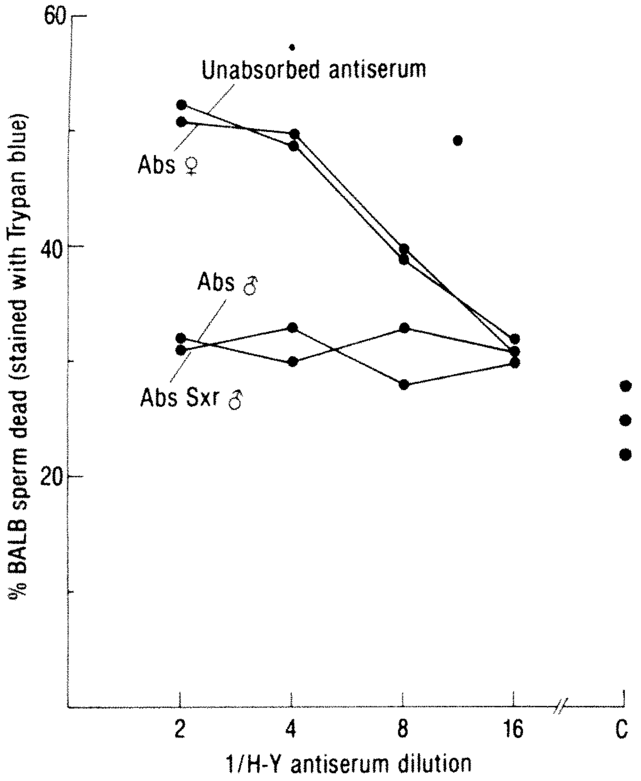

Fig. 2 Summary of cytotoxicity tests on mouse sperm with mouse H–Y antiserum after absorption with liver cells from normal females (B6), normal males (B6) and *Sxr*,XX males (see text). Abs, absorption with cells from the indicated sex. Each point represents an average value from three separate tests. C, control (complement included, antiserum omitted). Sperm suspensions were scored as coded samples. Tests were performed with BALB epididymal sperm according to Goldberg *et al.*[3], using serum raised in C57BL/6 (B6) female mice against B6 male spleen cells. Equal volumes (0.05 ml) of H–Y antiserum, sperm (5×10^6 per ml), and diluted rabbit serum (complement source) were incubated at 37 °C for 50 min. Trypan blue dye was added during the last 7 min of incubation to stain dead sperm. Absorption was accomplished by reacting 0.14 ml of H–Y antiserum (diluted 1/2) with an equal volume of packed liver cells. The cells were suspended in the antiserum for 30 min and then discarded. Absorption in the cytotoxicity test is manifested as a decrease in cytotoxic titre, indicating that H–Y antibody has been removed specifically from a particular aliquot by the cells used in the absorption procedure and that these cells must therefore contain H–Y antigen.

marker to distinguish the *Sxr*,XX male from the XY and *Sxr*,XY classes. Two types of mating are used: in one, *Sxr*,*Ta*/Y males are crossed with +/+ females (F_1 hybrid, C3H×101) and, in the other, *Sxr*,+Y males are crossed with *Ta*/+ females from a stock also maintained on the C3H/101 background. XY and *Sxr*,XY males are distinguished on the basis of testis weight and their ability to produce *Sxr*,XX progeny.

We tested *Sxr*,XX mice for the presence of H–Y antigen by the three methods described for *Tfm*/Y mice[5]. (1) In each of five separate experiments anti-H–Y serum gave a positive reaction in the cytotoxicity assay with dissociated epidermal cells from *Sxr*,XX males (Fig. 1*a*). In two of these experiments sibling XY males carrying *Sxr* (identifiable by small testes), and normal sibling XY males, were used as positive controls. In both experiments, one of which is shown in Fig. 1*b*, the anti-H–Y cytotoxicity reaction was stronger with *Sxr*,XY males than with normal XY males. This suggests the presence of excess H–Y antigen in *Sxr*,XY males (although this has not yet been corroborated by quantitative absorption of anti-H–Y serum) and thus might imply that *Sxr*,XY males have excess H–Y-determining genetic material. (2) The presence of H–Y antigen in *Sxr*,XX males was further indicated by a series of absorption tests; three of them, shown in Fig. 2, in which spleen, brain and liver cells of *Sxr*,XX males removed specific anti-H–Y reactivity from the H–Y antiserum. (3) C57BL/6 (B6) females grafted with *Sxr*,XX trunk skin were thereby specifically presensitised to give a second-set response when subsequently grafted with B6 male skin, indicating that the *Sxr*,XX skin graft was H–Y+ (Table 1).

These data support the interpretation that *Sxr* represents a cytologically undetected translocation between the Y chromosome and an autosome.

There are two possible mechanisms by which such a translocation may have arisen[1,2] (Fig. 3). If *Sxr* arose as a simple chromosome-type rearrangement between an autosome and the Y chromosome, the original male presumably possessed a normal complement of chromosome material, although the Y chromosome itself would be deficient and an autosome would carry a segment of Y chromosome. According to this scheme his *Sxr*,XX offspring would obtain a male-determining portion of the Y chromosome; his XY sons would have a deficient but nevertheless male-determining Y chromosome, and his *Sxr*,XY sons should have the same chromosome complement that was attributed to their father. But this hypothesis does not explain the defective testicular development seen in the original male or in his *Sxr*,XY sons[1] (reviewed in ref. 2). Therefore the more likely origin of this translocation involves a rearrangement of the chromatid-type in the father of the original male, in which case the original male could have retained a normal Y chromosome plus a duplication of a region of the Y chromosome involved in the translocation[1]. The defective testicular development of *Sxr*,XY males is understandable on the basis of this karyotype, since they would be partially equivalent to XYY males, which are known in the mouse to be subject to meiotic breakdown (reviewed in refs 2 and 6).

The interpretation of *Sxr* as a Y–autosome translocation may account for the different effect of *Sxr* on XX and XO genotypes. It has been proposed that the absence of germinal elements in XXY males arises because the presence of two active X chromosomes is incompatible with normal differentiation of male germ cells[7]. Early germ cell failure

Table 1 Second-set rejection of B6 male skin by B6 females previously grafted with *Sxr*,XX skin

First graft* (no. of B6 females grafted)	Rejection time (d) of B6 male skin grafted 2–3 months later							MST (confidence limits)
Sxr,XX (14)	10,	11,	12,	15,	15,	16,	16	14.5

	15,	16,	17,	17,	17,	21,	22	(16.3–12.9)
($C_3H \times 101$) F_1XX female controls (8)	14,	16,	21,	23,	23,	26,	28	20.5
	30							(17.2–24.4)

Summary of data for two experiments involving four *Sxr*,XX graft donors and three donors for each of the two control groups; these donors also provided spleen cells and tail-epidermal cells for serological tests (Figs 1 and 2). Trunk skin was grafted according to Billingham and Medawar[8], using Band-Aids instead of plaster casts; rejection times were scored visually. Median survival time (MST) and confidence limits of the median were calculated by the method of Litchfield[9].

Don't settle for half the literature loaf.

Now you can get the "whole" loaf with **BioResearch Index (Biol)**. Certainly **BIOSIS** selects, abstracts and indexes more than 140,000 primary journal articles every year . . . but there's more to life science literature than that. Much more.

In **Biol** we meticulously search and report on—

- Research Communications • Notes
- Reports • Symposia • Proceedings
- Meeting Abstracts • Monographs

These add up to 100,000 items which appear each month in **Biol** from thousands of sources.

You can leisurely browse the contents pages or quickly find special interests indexed by—

- Subject • Author • Field of Interest
- Organism (Biosystematic/Generic).

See what's in the oven throughout the entire world. Write or call today for full subscription information: **BioSciences Information Service of Biological Abstracts, Inc., Marketing Bureau, 2100 Arch Street, Philadelphia, Pa. 19103, U.S.A.**
Telephone—(215) LO 8-4016

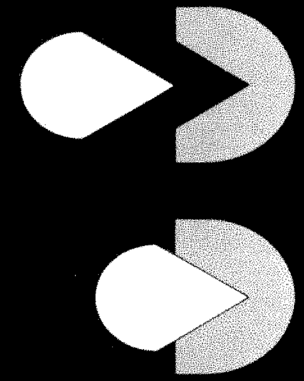
Cyclic AMP, GMP determination:

Second antibody sensitivity without second incubation



These new ^{125}I RIA kits from NEN combine extreme sensitivity with speed and convenience. We developed a very sensitive first antibody and pre-reacted it with a second antibody to eliminate the intermediate incubation.

Femtomole sensitivity is easily achieved by acetylation – with reagents provided in the kits.

There are other improvements, too. The iodinated tracer is exceptionally stable and is stored refrigerated, not frozen. Pipetting is done at room temperature. And a tritium-labeled marker is included to monitor sample recovery.

The resulting system is highly sensitive, accurate, reproducible, and yields low blanks.

Everything else is included for running 200 tubes – buffer, standards, complete protocol – even a telephone number if we can be of technical assistance. Ask us to send you our technical brochure.

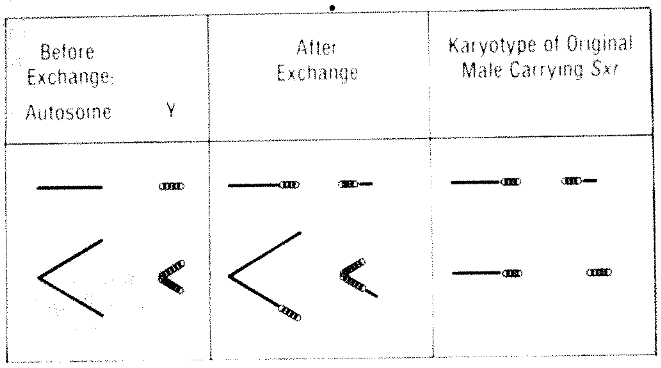

Fig. 3 Alternative hypotheses for translocational origin of *Sxr*. Upper, chromosome aberration; lower, chromatid aberration.

in *Sxr*,XX males and more extensive spermatogenesis in *Sxr*,XO males reinforces this argument. Furthermore, since spermiogenesis in *Sxr*,XO males is not completely normal, the translocated Y is presumably incomplete.

Although the data account for the male development of mice with an apparently female karyotype, different mechanisms must be responsible for the sex-reversed conditions found in goats and pigs (reviewed in refs 2 and 6). In these species the sex reversal is inherited as an autosomal recessive and this is not immediately understandable in terms of a Y–autosome translocation. Clearly, the H–Y status of these sex-reversed individuals requires investigation.

Time and mode of fusion of human fibroblasts treated with polyethylene glycol (PEG)

SOMATIC cell fusion has become a powerful tool in cell biology and genetics[1–3]. Until recently the standard reagent for increasing the rate of fusion in cultures of animal cells was inactivated Sendai virus[4]. In 1974 polymers of ethylene glycol (polyethylene glycol, PEG), over a wide range of molecular weights, were shown to be very effective, non-toxic chemical 'fusogens' for higher plant protoplasts[5]. They were then applied to fuse hen erythrocytes[6] and these with yeast protoplasts[7]. Applied to mammalian, including human, cultured somatic cells they yielded hybrid cells capable of indefinite multiplication[8,9]. Applied to somatic cell protoplasts of two species of higher plants, they yielded hybrid protoplasts which regenerated, multiplied and developed into whole hybrid plants[10]. The list of cells and cell organelles fused has now expanded to include bacterial and fungal protoplasts and chloroplasts. It is reasonable to expect that PEG will induce the fusion of almost any two biological membranes and become an increasingly useful tool in their investigation[6,11].

We report here two features of PEG-induced fusion in cultured human fibroblasts. One is that fusion occurs preferentially between, or near to the tips of elongated processes. The other is that, contrary to previous interpretations[8,9], fusion occurs very near to, or even during, the time of PEG treatment.

The proportions of bi- and multinucleate cells at various times after pulse treatment with PEG of monolayers of early passage human skin fibroblasts were measured both by phase contrast microscopy[8,9] and by fixing and staining. The time sequence is as follows: about one fifth of the final proportion of bi- and multinucleate cells are clearly identifiable as such within about 30 min at 37 °C after treatment this proportion goes on increasing over a number of hours (6 to more than 24) to reach a peak of 30–60% (Fig. 1). The gradual decline after this peak is an artefact not relevant to the present paper. However, two of the factors contributing to it were ascertained: (1) unfused cells multiply, while very few cells with three or more nuclei do so; (2) a proportion of binucleate cells undergo the reverse of fusion, that is, cell division without prior nuclear division. The proportion of binucleate cells which go on to fuse their nuclei is too small to contribute appreciably to the decline in question.

The gradual rise in the proportion of bi- and multinucleate cells over a number of hours after treatment was interpreted[8,9] as indicating that fusion of treated cells could continue over many hours after removal of PEG. A first doubt on this interpretation arose from the following observation. In rather sparse fibroblast monolayers, where each cell sends out pseudopodia to touch other cells, configurations like those of Fig. 2 are commonly seen a few hours

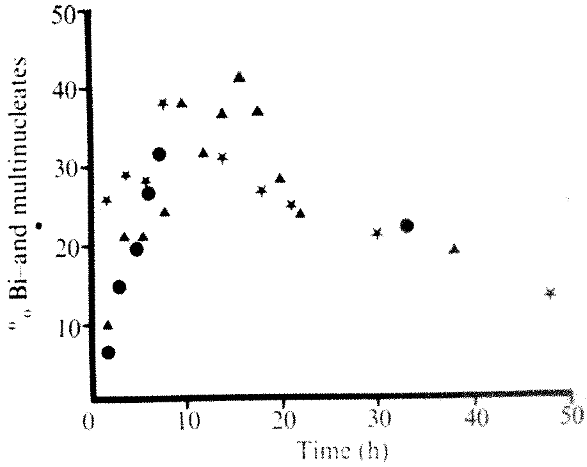

Fig. 1 Percentages of bi- and multinucleate cells at successive times after treatment of monolayers of human skin fibroblasts; PEG molecular weight 6,000, 50% (1w – 1v) in Dulbecco's medium for 1 min followed by washes in three progressively more diluted solutions of PEG and finally growth in Dulbecco's medium with 10% foetal calf serum. Different symbols represent different experiments. A variety of other effective treatments of monolayers with PEGs of different molecular weights, at different concentrations and with or without addition of dimethylsulphoxide[15] all show the same general trend: an initial increase with time of the proportions of bi- and multinucleate cells followed by a decline. For the meaning of this decline after the peak see text.

after treatment and before the peak proportion of bi- and multinucleate cells is reached. Points of contact between cells before treatment often involve a pair of thin elongated pseudopodia, one from each of two cells, or one pseudopodium from one cell in contact with the main body of another cell. Those pseudodopia which have fused following treatment later increase in diameter and contract in length. It takes time for two cells so connected to coalesce through an initially thin long connection. Two cells in the early stages of such coalescence would not be classified as a single binucleate cell. This mode of fusion is reminiscent of the fusion of myoblasts to form myocytes.

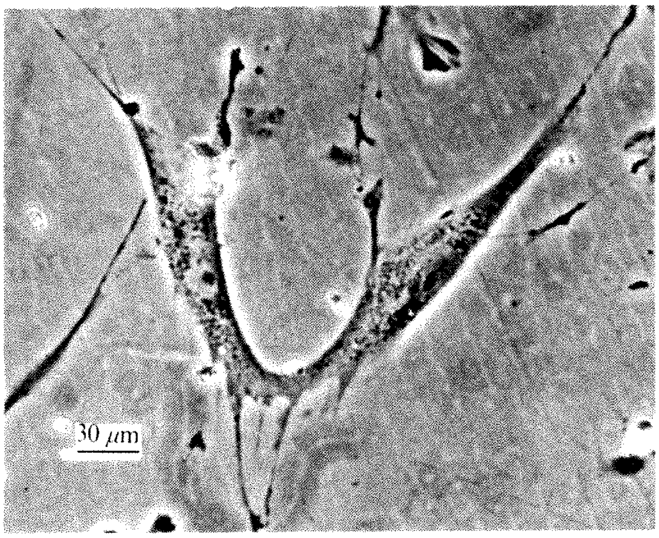

Fig. 2 Monolayer of human skin fibroblasts treated with PEG as in Fig. 1: a commonly seen configuration resulting from two cells which at the time of treatment fused at or near the tips of elongated filaments and gradually coalesced their cytoplasms. Phase contrast photography 3 h after treatment.

Time-lapse phase cinemicrophotography has provided an unequivocal answer. Applied to human fibroblasts in monolayer, treated for 1 min with 50% PEG (molecular weight 6,000), it has revealed three facts. First, some bi- and multinucleate cells are already classifiable as such soon after treatment. Second, apparently delayed 'fusions' are of the type just mentioned: two cells connected at the end of long thin pseudopodia coalesce their cytoplasms by slow contraction of these pseudopodia which fused near their tips at, or soon after, the time of treatment. The nuclei of such pairs of cells eventually come to lie next to each other in what has become a common cytoplasm, but this may take many hours. Third, time-lapse recording over more than 24 h of all the cells in individual fields has shown many cases of two cells initially far apart moving to touch each other. In no case, however, has fusion followed. If the increase with time of the proportion of bi- and multinucleate cells in monolayers were due to extensive fusion of such cells after removal of PEG we would have observed several such fusions.

Another kind of evidence comes from work on the time sequences of appearance of bi- and multinucleate cells in treated monolayers as compared with treated cell suspensions. The procedure developed by us and routinely used for treating cell suspensions[12] is to take up gently a well drained pellet of some 10^6 cells in 0.5 ml of PEG molecular weight 1,000 1w + 1.4v in Dulbecco's modified medium with 15% dimethylsulphoxide[13], dilute this suspension gently within 1 min with an equal volume of PEG molecular weight 1,000 1w + 3v without dimethylsulphoxide, and again with 4 ml of medium. This final suspension is then dispensed in flasks or dishes containing a volume of medium with serum at least 10 times greater. In contrast to treated monolayers (Fig. 1), the proportion of bi- and multinucleate cells classifiable as such from cells treated in suspension does not show the gradual rise in the first 24 h. The long time required by the cytoplasms of cells in monolayer to coalesce through thin long connections is not required by the rounded up cells of a suspension. It is important now to ascertain whether or not also in these cells fusion occurs prevalently between the tips of microvilli, or other microprocesses and, in general, between regions of high curvature.

Thus, as to the time of fusion, we conclude that whether two or more cells will ultimately coalesce and become recognisable as a single bi- or multinucleate cell is determined during or very near the time of treatment. In treated monolayers this final coalescence may take many hours, whereas in treated suspensions it occurs and can be recognised soon after treatment.

As to the mode of fusion, we conclude that in sparse monolayers it occurs mainly at or near the tips of filamentous processes of which every cell in low density cultures has many. This explains why the proportions of bi- and multinucleate cells found in treated sparse monolayers are as high as, or even higher than in confluent ones. In the latter, there is very extensive side-by-side contact between fibroblasts. Yet this does not lead to more fusion. It will be important to compare some of the physicochemical properties of the cell surface, such as charges, or distribution of intrinsic proteins, near the tips of processes with those on the main cell body (see for example refs 11 and 14). This preferential fusion near the tips of processes may well underlie the observation of a negative correlation between density of cells and proportion of mononucleate hybrids arising from PEG-treated mixed monolayers. This correlation was attributed to the lesser formation of large multinucleate cells in sparse monolayers. Instead it may well be the consequence, in part at least, of a greater fusion efficiency per cell in sparse monolayers due to the greater number of filamentous processes that fibroblasts show under this condition.

Loss of duplicate gene expression after polyploidisation

INCREASES in cellular DNA content have been important in the evolution of eukaryotes[1–3]. One mechanism for increasing DNA content is polyploidisation, which has been observed in a wide variety of organisms[4–8], and which is believed to have preceded the evolution of the early vertebrates[9]. It has been suggested that, following gene duplication, many of the redundant copies would be silenced early in evolution by mutation[10,11]. Those duplicate genes remaining expressed are then available to diverge in structure and acquire new functions[9]. We present evidence of extensive gene silencing in the 50-Myr history of a family of tetraploid fishes. Furthermore, those species regarded by systematists as advanced (that is, morphologically divergent from the ancestral form) may have lost the expression of more duplicate genes than primitive species (that is, those with a morphology similar to the ancestral form).

Theoretically, the most useful group of organisms for the analysis of gene loss after polyploidisation would be one which has undergone polyploidisation relatively recently (before complete diploidisation has taken place), yet not so recently that the enzymes encoded by the duplicate genes are still indistinguishable. The Catostomidae meet these requirements and thus provide an excellent model system for investigating genome evolution after polyploidisation. Since their origin 50 Myr ago[12], sufficient time has elapsed for many changes at the levels of morphology and structural genes. At the chromosome level, however, all genera have conserved a tetraploid karyotype with $2n=100$, compared with $2n=50$ for most cypriniformes[12]. In addition, the DNA content of catostomid species examined is twice that of typical diploid fishes[12]. On the basis of morphology these catostomids have been placed in three subfamilies. Two primitive subfamilies (Cycleptinae and Ictiobinae) closely resemble fossil forms (*Amyzon*, Miocene) in morphology[13–15]. A single advanced subfamily (Catostominae) has diverged considerably in morphology. Starch gel electrophoresis of 20 enzymes was employed to reveal the extent of duplicate gene expression. The application of Nei and Chakraborty's formula[16] for the probability of electrophoretic identity of two proteins, with a time span of 50×10^6 yr, allows us to estimate conservatively that the isozymes encoded by duplicate genes will be separable by electrophoresis at least 95% of the time.

The distributions of duplicate genes expressed are presented in Tables 1 and 2. Considerable extinction of gene expression has occurred. For the entire family, the average loss of duplicate gene function is 53% (range 35% to 65%). The average percentage is similar to that observed in the few species of salmonid[17] and cyprinid[18] fish which have been studied. In many cases where two catostomid species have the same percentage of duplications expressed, different combinations of loci have undergone the diploidisation process. There is no obvious correlation with the metabolic role of an enzyme and the extent to which the duplicate loci encoding it have undergone diploidisation.

Several lines of evidence argue against the genes being silenced randomly throughout the entire 50-Myr period. It is commonly assumed that one of the duplicate loci is free to accumulate what would have been previously 'forbidden' mutations as long as the other locus remains functional. Can the drift to fixation of non-functional (null) alleles over 50 Myr account for the amount of diploidisation observed in the catostomids? It has been shown[11] that the probability, P, of a null allele drifting to fixation at a duplicate locus is given by

$$P=1-[4Nu+1][\exp(-ut)] \qquad (1)$$

If we assume a typical mutation rate $u=1\times10^{-6}$ per peptide per generation[19,20], the number of generations, $t=25\times10^{6}$, and a 'generous' estimate of an effective population size for a typical catostomid species, $N=10^{9}$, then it is calculated that $P>0.9999$. On the basis of this theory most duplicate loci should have been lost after a 50-Myr period, a prediction which is in disagreement with our observation that only 53% (on the average) of the duplicate loci have been lost. Although null alleles may have drifted to fixation shortly after polyploidisation, it is unlikely that they are currently doing so. The fact that polymorphisms for null alleles have not been observed in the catostomids suggests that fixation occurs rapidly. An additional consideration is that many of the duplicate genes have diverged in their tissue and developmental specificity and are differentially regulated[9,21]. We have observed many instances of such differential regulation. The duplicate Ldh-B loci in *Catostomus commersoni*, for example, are equally expressed in mature gonads, while only one locus is expressed in most other tissues. Because some of the duplicate loci have diverged in function and regulation, and because we have observed levels of duplicate gene expression much higher than predicted by random loss, it is likely that these duplicate genes are at present being either maintained or quenched by selection.

An evolutionary trend of diploidisation can best be seen by investigation of a large number of genera. One important inference generated by the present study is that species of the primitive subfamilies have retained more functionally duplicate genes than those of the advanced subfamily. An

Average % of duplicate genes expressed = 59

The number of duplicate genes expressed for specific enzymes 50 Myr after tetraploidisation. The percentage of gene duplications still expressed is given for individual species of primitive catostomids. 2 indicates the presence of duplicate loci for an enzyme, 1 designates that only one locus is expressed. N* is the exact number of individuals examined for each locus for most species; however, for a few species, it represents an average among the loci studied. Late juvenile to adult fish were stored frozen, homogenised 1:2 (v/v) in Tris-HCl, pH 7, at 4 °C centrifuged 27,000g for 20 min, and the supernatant electrophoresed. Ak (adenylate kinase), Aat (aspartate amino transferase), Acp (acid phosphatases), Mdh (malate dehydrogenase—NAD), Pgm (phosphoglucomutase), and G3Pdh (glycerol-3-phosphate dehydrogenase-NAD) were resolved on histidine–NaOH buffer[25]; 6Pgd (6-phosphogluconate dehydrogenase–NADP), Ldh (lactate dehydrogenase–NAD), Ald (aldolase), and Sod (superoxide dismutase) on Tris-citrate[26]; Ck (creatine kinase), Gpi (glucose phosphate isomerase), and Sod on Tris–EDTA–borate[27]; Adh (alcohol dehydrogenase–NAD), and Xdh (xanthine dehydrogenase–NAD) on borate–NaOH[28]. Enzyme staining modified from Shaw and Prasad[29]. For most loci, various tissues were analysed. A diploid control, *Notropis stramineus*, showed no evidence of gene duplication.

Average % of gene duplications expressed 42

The number of duplicate genes expressed for specific enzymes 50 Myr after tetraploidisation. The percentage of gene duplications still expressed is given for individual species of advanced catostomids. 2 indicates the presence of duplicate loci for an enzyme, 1 designates that only one locus is expressed. Abbreviations and methods are as explained in Table 1.

average of 59% of the loci show evidence of duplication in the primitives (12/20) compared to 42% in the advanced (8/20). Within the advanced subfamily, relatively primitive species such as *Moxostoma cervinum*[22] and *C. commersoni*[23] have more functionally duplicate genes than highly morphologically divergent species such as *M. rhothoecum* and *C. plebeius* (see Table 2). If the quenching of genes were completely random through time, or if tandem duplications occurred to any extent, the above relationship would not be evident. A phylogeny has been constructed, based on the comparison of the presence of one or two functioning gene loci, which yields a 'tree' similar in many respects with those based on morphology. From these considerations we conclude that species which are conservative at the morphological level are also conservative with respect to the retention of duplicate gene expression. In an analysis parallel to our study, Hinegardner[24] has found that the more generalised fish orders have higher cellular DNA contents than highly specialised orders. Our working hypothesis is that phenotypically advanced organisms lose more genetic information. After an initial DNA increase by polyploidy, the first stage of evolution will be a moderately rapid loss of the expression of redundant genes, as found in the catostomids. Then, over a longer period, this DNA which is not expressed is physically eliminated[24]. The catostomids are probably still in the first stage in view of their high DNA content.

In summary, during 50 Myr of post-polyploid evolution, the catostomids have returned to a functionally diploid state at over half the enzyme loci examined. This process is not entirely random. We suggest that some duplicate genes have been quenched more rapidly in the morphologically advanced species than in the morphologically conservative species.

We thank the many individuals who provided specimens. This research was supported by grants from NSF and NIH.

Common precursor pathways of Herpes DNA and of repair synthesis in ultraviolet irradiated cells

DEOXYRIBONUCLEOTIDE precursors of DNA synthesis may be supplied by two alternative pathways in mammalian cells[1]: (1) endogenous synthesis by reduction of the corresponding ribonucleotides at the diphosphate level, except thymidine nucleotides which are produced by deamination and methylation of cytidine deoxynucleotides at the monophosphate level; (2) exogenous salvage synthesis by stepwise phosphorylation of pre-existing deoxyribonucleosides. The first step leading to monophosphates is catalysed by purine[2] and pyrimidine[3,4] deoxyribonucleoside kinases. In cells infected with Herpes simplex type 1 (HSV) there is an induction of both thymidine kinase (TK)[5] and deoxycytidine kinase activity[6]. These two activities seem to be a property of the same virus-specified enzyme[7], whose role

Table 1 Effects of inhibitors of endogenous pathways on HSV production by ultraviolet-irradiated and non-irradiated stationary CV-1 cells

	Dose of ultraviolet (erg mm^{-2})			
	0	120	240	480
Treatment	Virus yield as % of the corresponding non-treated cultures			
None	100 (1.3×10^9†)	100 (3.1×10^8†)	100 (9.1×10^7†)	100 (2.3×10^7†)
Hydroxyurea, 10 mM	0.8–1.3‡	3.6	3.0	3.3–4.5‡
Cytosine arabinoside, 0.1 mM	0.2–0.4	0.65	1.4	2.7–3.5
Fluorodeoxyuridine, 2 mM	7–12	22	45	67–87
FUdR, 2 mM + thymidine 2 mM	64–71	—	—	187–207
Thymidine, 2 mM	55–70	—	—	123–144

Stationary CV-1 cultures (2×10^5 cells cm^{-2}) were kept before irradiation and infection with HSV in the presence of a minimum essential medium (MEM) without serum and tryptose phosphate broth, as previously described[10]. HSV was grown in the presence of MEM. The viral yield by control cultures was between 150 and 350 PFU per cell.

*The drugs were present during the 18 h of the viral cycle.

†PFU per Petri dish in the non-treated cultures.

‡Extreme values of three separate experiments.

remains unclear. It seems to be important for viral DNA synthesis in resting cells[5] in which the endogenous metabolism of DNA is low whereas the degradative phosphatase activity is high[9]. On the other hand viral TK activity increased faster during the exponential phase of viral DNA synthesis in cells irradiated with ultraviolet light before infection than in non-irradiated cells[10]. This suggested that viral TK may have a more important role in the synthesis of HSV DNA in ultraviolet-irradiated than in non-irradiated cells. I present here results showing that the exogenous pathways are preferentially used for both HSV replication and for DNA repair synthesis in ultraviolet-irradiated cells.

All experiments were performed in stationary (2×10^5 cells cm^{-2}) monkey kidney CV-1 cells. Culture, irradiation and infection of cells and the measurements of single cycle virus yield were carried out as previously described[10].

First, I measured the production of infectious virus by irradiated and control cultures in the presence of inhibitors of endogenous pathways such as fluorodeoxyuridine (FUdR) and cytosine arabinoside (ara-Cdr) which block the synthesis of deoxythymidilate[11] and of deoxycytidilate[12], respectively, and hydroxyurea (HU) which mainly inhibits the reduction of ribo- to deoxyribonucleotides[13,14]. Table 1 shows that viral production was more inhibited by these drugs in control than in irradiated cultures. The extent of inhibition of viral production by FUdR and ara-Cdr decreased as the dose of ultraviolet increased. Since both drugs must be phosphorylated in order to inhibit DNA synthesis[11,15,16], this effect could be due to a lower rate of phosphorylation of these inhibitors as a consequence of ultraviolet irradiation. I found that FUdR and deoxycytidine were phosphorylated to a lesser extent in extracts from ultraviolet-irradiated and infected cells than in extracts from controls (data not shown). HSV production was no longer impaired in the presence of both thymidine and FUdR (2 mM each) in non-irradiated cultures (Table 1). This might indicate that the exogenous supply of thymidine nucleotides is sufficient under these conditions to overcome the corresponding endogenous block induced by FUdR. However, one cannot exclude the possibility that viral and (or) cell TK have greater affinity for thymidine than for FUdR, leading to a lower rate of phosphorylation of the latter drug. In addition, Table 1 shows that in the presence of thymidine alone (2 mM) HSV production decreased in non-irradiated cultures and increased in irradiated cultures.

I measured in parallel the amount of incorporation of the four deoxyribonucleosides into DNA of uninfected cells in the presence of these inhibitors. This incorporation was more inhibited in control than in irradiated cultures (Table 2). The pool sizes of the free deoxyribonucleosides are unknown but probably differ in the two conditions since they depend on the rate of formation and of disappearance of deoxyribonucleosides which are both altered after irradiation as a result of the increase in nuclease activities leading to free deoxyribonucleosides[17] and by the depression of the rate of DNA synthesis[18]. As the deoxyribonucleoside concentrations used here (3×10^{-7} M) are sufficient to modify the natural pool size of the free deoxyribonucleosides occurring in normal cultures[19], it is not possible to obtain quantitative data from these last results. It can only be concluded that inhibitors of endogenous DNA synthesis are less effective (1) on the replication of HSV in ultraviolet-irradiated cells than in control cultures, (2) on the incorporation of the four deoxyribonucleosides into cellular DNA during post-ultraviolet DNA synthesis than during normal synthesis.

Table 2 Incorporation of deoxyribonucleosides into the DNA of normally growing and stationary ultraviolet-irradiated CV-1 cells in the presence of inhibitors of endogenous pathways

	Incorpotation as % of controls of:							
Treatment	Deoxyadenosine		Deoxycytidine		Deoxyguanosine		Thymidine	
	A*	B*	A	B	A	B	A	B
None	100 (9,975†)	100 (1,850†)	100 (3,360)	100 (1,060)	100 (10,810)	100 (2,620)	100 (19,320)	100 (3,990)
Fluorodeoxyuridine, 1 mM	48	86	32.6	49.5	46	60	43	117
Cytosine arabinoside, 0.1 mM	20.2	50	12.3	35	24.2	36	7	30
Hydroxyurea, 10 mM	15.1	55	33	360	12.7	51.5	4.9	30.6

CV-1 cells were grown in 3 cm diameter Petris dishes, then kept in the presence of each of the ^{3}H-deoxyribonucleosides at 2 μCi ml^{-1} + the four unlabelled deoxyribonucleosides to obtain a final concentration of 0.3 nmol ml^{-1} each, in MEM without serum (stationary) or with 5% dialysed newborn calf serum (growing). After 18 h, cells were rinsed three times with PBS, scraped into PBS, ultrasonicated (2 min at 4 °C), treated with DNAse-free pancreatic RNAse (20 μg ml^{-1}, 3 h at 37 °C) to digest the labelled RNA, then the 5% TCA-insoluble radioactivity was precipitated on to GF/C filters and counted as described[10]. The given values are the mean values of three Petri dishes.

*A, growing (3×10^4 cells cm^{-2}) cultures.

B, stationary ultraviolet-irradiated (240 erg mm^{-2}) cultures.

†Actual values for c.p.m. per Petri dish in the controls (mean values of three dishes).

The mechanism by which inhibitors of endogenous pathways decrease the incorporation of labelled deoxyribonucleosides by the exogenous pathways during normal DNA synthesis remains unknown. The cyclic increase of the TK activity at the beginning of the S phase[19] strongly suggests that the corresponding exogenous pathway has an important role in normal DNA synthesis, possibly as a salvage pathway[20]. An interrelated use of both endogenous and exogenous pathways could explain the mechanism mentioned above. In contrast, the excision-repair synthesis which occurs in these stationary ultraviolet irradiated CV-1 cells in the absence of normal DNA synthesis[10] would necessitate a low concentration of deoxyribonucleosides. This could be achieved by the exogenous pathways which are economical since (1) they permit the re-utilisation of the breakdown products arising from the irradiated DNA as previously shown[10], (2) they require only phosphorylating enzymes compared with the numerous enzymes involved in the endogenous pathways.

To test this last possibility I measured the level of the four deoxyribonucleoside kinases in extracts of stationary cultures made at different times after irradiation during the 48-h period[10], and found that the deoxyribonucleoside kinase activities decreased slightly by 6 h after irradiation, then increased, attaining a value at 24 h which was greater than that found prior to irradiation (Table 3).

Table 3 Phosphorylating activities of extracts of stationary CV-1 cells at different times after ultraviolet irradiation

^{3}H-precursor	Time (h) after irradiation with 240 erg mm^{-2}				
	0	6	12	24	48
Deoxycytidine	100 (1†)	62*	111*	140*	106*
Deoxyguanosine	100 (0.98)	77	122	128	110
Thymidine	100 (2.41)	85	119	141	126

Stationary cultures were kept in MFM without calf serum and tryptose phosphate broth between irradiation and extraction. Cell extracts were made and their enzyme content determined as described by Lin and Munyon[21]. For each cell extract at least three dilutions were tested over a range of protein concentrations where the reaction was linear (500–3,000 μg ml^{-1}). The final concentrations of the non-radioactive deoxyribonucleosides in the mixture reactions were, for deoxyadenosine and desoxyguanosine: 4×10^{-6} M; for deoxycytidine and thymidine: 2×10^{-5} M.

*The values are given as the percentage of the values obtained at time 0.

†nmol of deoxyribonucleoside phosphorylated per mg protein in 30 min at 38 °C.

The activity of deoxyadenosine kinase was too low to be detected in these conditions. The variations of the deoxyribonucleoside kinase activities observed after ultraviolet irradiation seem not to be due to the occurrence of any normal DNA synthesis, since similar results (unpublished observation) were obtained in extracts from cells kept in the presence of 2 mM of each of the four deoxyribonucleosides after irradiation, that is, in conditions where normal DNA synthesis must be inhibited by an excess of non-radioactive deoxyribonuclosides[22,23]. The increase of these kinase activities starting 6 h after irradiation could reflect either the ultraviolet-induced synthesis of new enzyme molecules, or the alterations of the activities of pre-existing enzymes, for example by small effector molecules like dTTP[19] leading to an end-product inhibition. Moreover, these results suggest a role of the deoxyribonucleoside kinases in DNA repair synthesis since their activities attain a maximum level at about the same time (24 h) at which DNA template function is fully restored, as shown by the recovery of interferon mRNA production[24] and of 45S ribosomal RNA transcription[25] in ultraviolet-irradiated stationary CV-1 cells.

In conclusion, it seems that deoxyribonucleoside precursors of DNA synthesis are supplied essentially by the exogenous pathways in post-ultraviolet DNA synthesis whereas in non-irradiated cells both exogenous and endogenous pathways are important in CV-1 cells. A similar pattern seems to occur for DNA synthesis of HSV grown in ultraviolet CV-1 cells as compared with virus grown in control cells. This conclusion is drawn from our earlier results[10] and from those obtained with inhibitors of endogenous pathways of cell and of viral[26,27] DNA synthesis. Such a pattern could explain that in the presence of thymidine at high concentrations, HSV production is slightly impaired in control cultures and increased in irradiated cultures (Table 1).

These results would indicate that the metabolic pathways are common to host cell and to HSV DNA synthesis. In this case, there might be a correlation between the residual ability to support HSV replication and the extent of repair synthesis in different ultraviolet-irradiated cell lines. I am currently investigating this possibility using normal skin cells and xeroderma pigmentosum cell lines which are defective in ultraviolet-induced repair synthesis.

This work was supported by an INSERM contract. I thank Dr J. Lewis for reviewing the manuscript and S. Nocentini for discussions.

Maternal histidine metabolism and its effect on foetal development in the mouse

THERE have been reports[1,2] of possible deleterious effects on the mental development of children due to maternal histidinaemia, in which a deficiency of the enzyme histidase leads to the exposure of the foetus to abnormally high concentrations of histidine and its imidazole derivatives. This is analagous to the well established case of maternal phenylketonuria[3] which can lead to mental retardation in metabolically normal children. There is also a suggested link[4] between low maternal concentrations of two enzymes in galactose metabolism and infantile cataracts. We report

The normal diet was FFG/LAC (Fox Foods) ground into a powder and fed as damp mash *ad libitum* at 1700 h each day with or without additives (% by weight), histidine-HCl, phenylalanine, lysine, proline (Sigma). Because of the diurnal variation in feeding, the plasma values shown are not present during the whole 24 h. Blood was taken between 0900 and 1000 h. We have evidence that higher levels are present in the early morning and that by 1700 h the levels can drop to about 50%. The low histidine diet was a mixture of 75% histidine-free diet (HF-2, Cow and Gate) 25% normal diet plus 2% vitamin supplement (Nutritional Biochemicals). All determinations of amino acids were carried out by ion exchange column chromatography (ninhydrin) with α-guanidoproprionic acid as an 'external' standard added before deproteinisation by sulphosalyclic acid. All are expressed as μmol ml^{-1} with their standard errors.

here work on the nature of the maternal effects of histidinaemia using mutant mice which are the homologues of the human condition[5–7].

The activity of histidase is very low in the mouse mutant homozygotes (*his/his*<5% activity of +/+) resulting in up to 20 times the normal level of histidine and its derivatives in all tissues. Heterozygotes, with about 50% enzyme activity, have normal histidine levels on normal diets[5,6]. The histidinaemic mice have no overt abnormalities. On the other hand, some offspring of histidinaemic mothers, even when such offspring are metabolically normal, (*his/*+), display a balance defect resulting in circling behaviour which is associated with some or all of the following: deafness, damage during development *in utero*[5,6] to the canals, cochlea and otoliths of the inner ear.

We have now found that this maternal effect can also be produced by high histidine diet of pregnant mothers who, on normal diet, would give birth to normal offspring. We have also established that the middle third of pregnancy is the critical period. Conversely, it is possible to reduce the incidence of abnormal offspring of genetically histidinaemic mothers by reducing the histidine content of their diet during the second week of pregnancy. The exposure of the foetus to abnormal metabolic conditions of the mother, is, however, not the only determining factor for this condition. It seems that the genetic background can play an important role in influencing the susceptibility of the foetus to the metabolically generated teratogen. The murine maternal histidinaemia discussed here may well be of relevance to the aetiology of the homologous human abnormalities.

We were able to induce histidinaemia by purely dietary means. When heterozygous mice (*his*/×) are placed on an 8% histidine-supplemented diet the levels approach those of histidinaemic mice; homozygous wild-type mice (+/+) on this diet have only slightly higher levels than normal and were not used (Table 1). When we fed this diet to heterozygotes during the second week of pregnancy 14 balance defective offspring were produced out of 130 in 21 litters, compared with none in 209 animals on unsupplemented diet. No abnormal offspring were obtained from mothers fed the special diet during the first or third week. The critical period parallels that for *in utero* damage of the ear

Table 2 Effect of an 8% histidine-supplemented diet during the second week of pregnancy on the offspring of heterozygous (*his/*+) mothers

Diet	No. of offspring	Offspring genotypes	Effect on Balance	Effect on Hearing	Effect on inner ear Left Canals	Effect on inner ear Left Otoliths	Effect on inner ear Right Canals	Effect on inner ear Right Otoliths
(*a*) Offspring of mothers on 8% supplement	3	1 *his/his*; 2 *his/*+	Severe	Severe	Abnormal	Missing	Abnormal	Missing
	1	*his/his*	Mild	Mild	Normal	Missing	—	—
	1	*his/*+	Mild	Severe	Abnormal	Missing	Normal	Missing
	1	*his/his*	Normal	Mild	Normal	Missing	Abnormal	Missing
	2	2 *his/*+	Normal	Mild	Normal	Missing	Normal	Missing
	1	*his/*+	Mild	Normal	Abnormal	Altered	Abnormal	Altered
	2	2 *his/*+	Normal	Normal	Abnormal	Missing	Abnormal	Missing
	12	8 *his/his*; 4 *his/*+	Normal	Normal	Normal	Missing	Normal	Missing
	11	5 *his/his*; 6 *his/*+	Normal	Normal	Normal	Normal	Normal	Normal
(*b*) Offspring of untreated mothers	19	11 *his/his*; 8 *his/*+	Normal	Normal	Normal	Normal	Normal	Normal

The mice used were of 50% Peru/50% C57BL background. The treated and untreated animals were contemporaries so that variation in penetrance of the balance defect due to relaxation of selection (see text) was not relevant. The heterozygous (*his/*+) mothers were mated to homozygous (*his/his*) fathers so that the offspring listed above were 50% *his/his*, 50% *his/*+. Some of each genotype were affected. Balance was tested by spinning the animal by the tail and observing in a perspex cage. The animal was severely affected if it circled and mildly if it leant its head on one side[1,2]. Hearing was tested with a short, sharp high pitched noise when the animal was at rest. A severe effect was no reaction of the ears or body any time the animal was tested and mild was no reaction 50% of the time. It can be seen that an effect on balance is only observed when both canals and otoliths are affected.

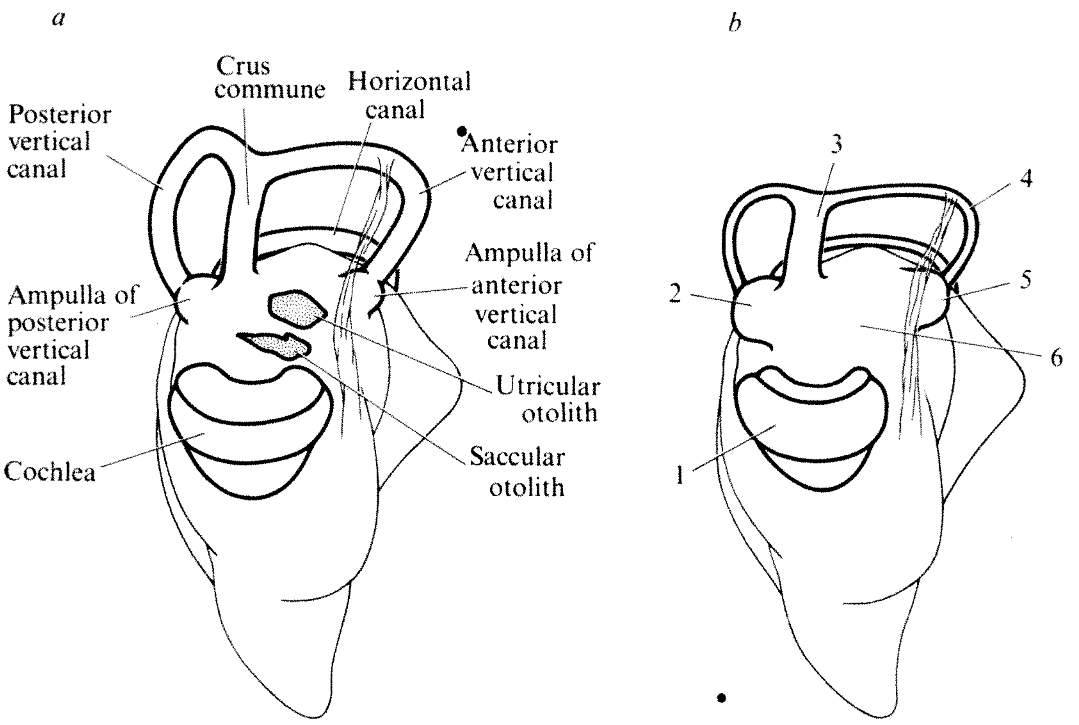

Fig. 1 Diagram of the abnormalities seen in the whole mounts of adult ears. *a*, Normal; *b*, affected. The ears were dissected into 75% alcohol and eventually cleared in benzyl alcohol. They were examined under the normal light and polarised light microscope. Canals are considered abnormal if they are shortened, thin or misshapen; otoliths are altered if they are enlarged or thin. About half the offspring from both treated and untreated mothers have utricular or saccular otoliths displaced but not damaged. This occurs in animals of the Peru or hybrid Peru/C57BL strains but not with pure C57BL. Any one ear may show one or more of the following abnormalities. 1, Enlarged or distorted cochlea; 2 and 5, enlarged ampullae; 3, shortened crus commune; 4, canals thin or misshapen; 6, otoliths absent, or thin or large crystals.

by X irradiation (9–16 d) (ref. 8). Details of the behaviour and effects on the vestibule of some of these offspring are shown in Table 2. The lesions in the balance defective animals are similar to those of balance defective offspring of genetically histidinaemic mothers[6] (Fig. 1). Some of the offspring without balance defects show subclinical levels of vestibular damage (Table 2*a*), as has been observed in some offspring histidinaemic mothers[6]. Offspring of untreated, metabolically normal females of the same stock show no clinical or subclinical lesions (Table 2*b*). Thus high maternal levels of histidine or its derivatives, however produced, are necessary for the production of balance defective offspring.

It is also possible to modify plasma histidine levels in histidinaemic (*his/his*) mothers during this critical second week of pregnancy. Histidine levels can be increased two to threefold further by a 2% histidine-supplemented diet and, of more importance, histidine levels can be reduced to about 10% (approaching *his*/+ or +/+ levels) by a low histidine diet (Table 1). The behaviour of offspring of mothers who received these diets is shown in Table 3. The 2% histidine-supplemented diet (which doubles the plasma histidine levels) did not significantly increase the proportion of balance defective offspring.

Table 3 Effect of a 2% histidine-suplemented diet, normal diet and low histidine diet, during the second week of pregnancy on the offspring of homozygous (*his/his*) mothers

Diet	No. of litters	No. of animals	Effect on balance Severe	Mild	Normal	% Affected	χ^2	P
(+)2% Histidine	23	79	12	10	57	27.8	1.15	ns
Normal	22	94	11	13	70	25.5	—	—
Low histidine	20	65	0	2	63	3.1	25.2	< 0.001

Genetic background of the animals, diet and scoring of the balance defect were as for Tables 1 and 2. The number of offspring with their balance severely affected, mildly affected and unaffected were tested by χ^2 test for both the 2% histidine-supplemented diet and the low histidine diet against the expected numbers on the normal diet.
ns, not significant

The histidine in untreated *his/his* mothers therefore, must lie above a 'saturation level' beyond which histidine levels are no longer relevant in determining the proportion of affected offspring. This conclusion is reinforced by the observations, previously described[6], that in any one litter there may be affected and unaffected offspring although all will have been exposed to the same maternal metabolites. In these circumstances other factors must be involved in the variation within and between litters. The low histidine diet, however, decreased the proportion of balance-defective offspring from 26% to 3%. In the lower range maternal histidine levels are therefore critical in determining the frequency and severity of balance defective offspring.

High levels of other amino acids (Table 1) during pregnancy do not have the same effect as histidine. Mice, homozygous for the gene *Pro-1*^{n} (refs 9–11) have <5% proline oxidase activity with consequent high levels of proline in their tissues. We have found that such prolinaemic mothers on a normal diet or fed a 2% proline-supplemented diet do not produce balance-defective offspring although their plasma proline is as high as plasma histidine in histidinaemics. Similarly, pregnant C57BL mice were fed on either 5% or 10% lysine or phenylalanine-supplemented diet in the, critical, second week of pregnancy. These diets increase plasma lysine or phenylalanine genes evolve independently in the model. Hence the probability $P_{N_0\to 0}(t)$ that all are extinct at time t is

$$P_{N_0\to 0}(t) = P^{N_0} = \left(\frac{t}{t+2N_0}\right)^{N_0} \qquad (12)$$

while the probability that only one survives, $P_{N\to 1}(t)$, is

$$P_{N_0\to 1}(t) = N_0(1-P_0)P^{N_0-1} = \frac{2N_0^2 t^{N_0-1}}{(t+2N_0)^{N_0}} \qquad (13)$$

The rate of change of the sum of these two probabilities gives the rate at which the number of surviving genes is reduced to one, that is the rate of gene fixation,

$$\frac{\mathrm{d}p_f(t)}{\mathrm{d}t}$$

Thus

$$\frac{\mathrm{d}p_f(t)}{\mathrm{d}t} = \frac{\mathrm{d}P_{N_0\to 0}}{\mathrm{d}t} + \frac{\mathrm{d}P_{N_0\to 1}}{\mathrm{d}t} = \frac{4N_0^2(N_0-1)t^{N_0-2}}{(t+2N_0)^{N_0+1}} \qquad (14)$$

With this rate, the cumulative probability of gene fixation by time t, $p_f(t)$, is

$$P_f(t) = \int_0^t \frac{\mathrm{d}p_f(t')}{\mathrm{d}t}\,\mathrm{d}t' = \frac{(2N_0^2+t)t^{N_0-1}}{(t+2N_0)^{N_0}} \xrightarrow[t\to\infty]{} 1 \qquad (15)$$

so that gene fixation always takes place and

$$\int_0^t \frac{\mathrm{d}p_f(t')}{\mathrm{d}t}\,\mathrm{d}t' = \frac{2N_0(N_0-1)t^{N_0}}{(t+2N_0)^{N_0}} \xrightarrow[t\to\infty]{} 2N_0(N_0-1) \qquad (16)$$

so that equation (11) gives the mean time to fixation in the birth and death model. Because one gene always becomes fixed, the probability of ultimate fixation of any particular gene is $1/N_0$.

Alternatively, Black and Gibson[29] measure the percentage of genes that become extinct. For example, from equation (9) the mean time it takes for 99% of the genes to become extinct is given by

$$0.99 = \frac{t}{2N_0 + t} \text{ or } t = 198N_0$$

If $N_0 = 100$, then one would expect that only one gene would remain after 19,800 crossovers. But since the mean value of $N(t)$ is N_0, given that one gene remained, one would expect to find it present in 100 copies. As Fig 3 shows, $P_0(t)$ rises rapidly, reaches 0.9 by $t = 18N_0$, and then slowly approaches its asymptotic value of 1.0. Thus this measure of the fixation time is very sensitive to the percentage criteria used when more than 90% extinction is specified. For example, while it takes 19,800 crossovers to attain 99% extinction of 100 genes, only 1,800 crossovers are required to reach 90% extinction Further, if one wishes to determine the dependence of the fixation time on N_0, a percentage fixation time is not suitable, for example, 99% elimination for $N_0 = 10^2$ and 10^6 leaves 1 and 10^4 remaining genes, respectively.

Estimates for the gene fixation time obtained from the birth–death model can be compared with Smith's[27] Monte-Carlo results. Smith lets $N(t)$ vary within set limits, chooses $p = 1/2$, and allows mispairing by a random number of positions as long as it is consistent with the prescribed latitude for $N(t)$. As a criterion for fixation he requires that the "clonality"

$$\left[\sum_{i=1}^{N_0}\left(\frac{n_i(t)}{N(t)}\right)^2\right]^{1/2} = 0.9$$

This criterion, which is roughly equivalent to requiring that 95% of the family be composed of copies of a single repeat, can be compared with requiring $n_i = 0.95\,N_0$ in our model Then the time at which $P_{0\,95N_0}$ is a maximum would logically correspond to Smith's fixation time. For the birth–death model this time, $t = (0.95N_0 - 1)N_0$ given by equation (6a), will vary quadratically with N_0 for large N_0. Smith found that fixation time increased approximately linearly with N_0. Further, say for $N_0 = 500$, Smith finds fixation times of the order of 10^4 crossovers, whereas the linear birth death model predicts $t \sim 2.4 \times 10^6$. Equation (11) which requires a more stringent fixation condition predicts $T_{bd} \sim 5 \times 10^5$. These discrepancies with Smith's simulations are due to the fact that random mispairings by more than one repeat were allowed in the simulations

Alternative models

In the model we have just considered, time has been measured in units of crossover events. If the number of crossovers within the multigene family per cell division were constant this approach would be appropriate One can, however, envision the situation in which the number of crossovers that occur per unit time is proportional to the number of homologous genes in the family Southern[35] has suggested that such a mechanism may account for the periodicities seen in mouse satellite DNA. Thus, suppose the rate of crossingover influencing gene i is proportional to n_i so that $\lambda_{n_i} = kpn_i$ and $\mu_{n_i} = k(1-p)n_i$, where k is the crossover rate per gene copy. For $p = 1/2$ this model is equivalent to the previous one with $N(t)$ replaced by k^{-1}. Thus it has the advantage of not requiring that $N(t)$ be approximated by its mean value, which for $p \neq 1/2$ would be time dependent. Hence, in this model, selective advantage (disadvantage) of a gene could be represented by using the known solutions to the linear birth–death problem[38] for $p > 1/2$ ($p < 1/2$).

A third model which leads to somewhat different results is to view the changes occurring at gene i as a gambler's ruin problem[38]. That is, if we assume that there exists some biological mechanism for maintaining the length of the multigene family constant, say at N_0, then gene i can contract until all copies are lost or it can expand until it attains length N_0. We may again assume that there are equal probabilities for gene i expanding and contracting by one copy, that is $p = 1/2$. If gene i attains length N_0, then all other genes are necessarily lost and gene i has been fixed. Since we have introduced no bias among the genes, the probability that gene i is fixed is $1/N_0$ and the probability that it is lost is $1 - 1/N_0$. When $p \neq 1/2$, as in a simulation of selective pressure, the probability of gene i being fixed is

$$\left(\frac{q}{p}-1\right)\Big/\left[\left(\frac{q}{p}\right)^{N_0}-1\right]$$

where $q = 1-p$ (ref. 38). As in the first model, one might suppose that the crossover probability per unit time for influencing genes i is n_i/N_0. Using results on conditioned random walks developed in another context[38], we can estimate the mean time to gene fixation, T_{gr}, measured in crossover events and determined by a gambler's ruin process, as

$$T_{gr} = \begin{cases} (N_0-1)N_0 & p = 1/2 \\ \dfrac{N_0}{|q-p|}\ln\dfrac{N_0 + \sqrt{N_0^2 + 4S(S-1)}}{2S} & p \neq 1/2 \end{cases} \qquad (17)$$

where $S = p/(p-q)$ for $p > 1/2$ and $S = q\,(q-p)$ for $p < 1/2$. Smith personal communication obtained the same conclusion for $p = 1/2$ using Kimura's results on the fixation of mutant genes, and W. A. Beyer and M. S. Waterman (personal communication) have shown the result to be asymptotically valid as N_0 gets large. The corresponding time for the first model with $p = 1/2$, obtained by setting the clonality to 0.9 is $t = (0.95\,N_0 - 1)N_0$, while the estimate obtained by setting $M_0(t) = N_0 - 1$ (see equation (11)) is precisely twice as long as that given by equation (17)

It is difficult to envision a biological process that would keep $N(t)$ constant If the fitness of an organism is maximal when $N = N_0$

crossover, with probability 1/2, one repeat will be eliminated, leaving no copies of it in the family. With the same probability some other repeat will be duplicated, leaving two copies of it. At a later stage in the process a repeat may have many copies, but there may still occur a streak of bad luck which leads to its elimination. Eventually, this will have occurred to all but one repeat. This repeat will then be fixed, and for $p = 1/2$, on the average, there will be N_0 copies of this repeat. As the process of unequal crossing over continues, the number of copies of this remaining repeat may also reach zero. In fact, the probability of this occurring will approach 1, but only as the number of crossovers approaches infinity. Since evolution only has had a finite time to proceed, this case is of no interest. Also, in reality, the loss of the genome would be highly selected against.

To assess the validity of replacing $N(t)$ by its mean value N_0 one can compare the results of Monte-Carlo simulations with our analytical results. Black and Gibson[29] performed such a simulation. They assumed that mispairing by one repeat occurs before each crossover, that $p = 1/2$, and they did not require that $N(t)$ remain constant. If one compares the Black and Gibson results for the percentage of the original gene types that remain in the family after a given number of crossovers with the predictions of the linear birth–death model one finds qualitative agreement (Fig. 2). The slight quantitative disagreement, especially at small values of N_0, may stem from our setting $N(t) = N_0$, or may be due to poor statistics in the Monte-Carlo simulations which start with few repeats.

In Fig. 3 we plot $P_{n_i}(t)$ for n_i between 0 and 4. For $n_i > 1$ the maximum of P_{n_i} occurs at

$$t = (n_i - 1)N_0 \tag{6a}$$

and has the value

$$(P_{n_i})_{\max} = \left(\frac{2}{n_i - 1}\right)^2 \left(\frac{n_i - 1}{n_i + 1}\right)^{n_i + 1} \tag{6b}$$

The probability of finding exactly n_i copies of the ith repeat decreases after $t = (n_i - 1)N_0$ partially due to the further duplication of this repeat. The probability $P_{n \geq n_i}(t)$ or finding n_i or more copies of the repeat is, for $n_i \geq 1$, given by

$$P_{n \geq n_i}(t) = \frac{2N_0}{t}\left[\left(\frac{t}{2N_0 + t}\right)^{n_i} - \left(\frac{t}{2N_0 + t}\right)^{N_0 + 1}\right] \tag{7}$$

which for $N_0 \gg n_i$ is approximately given by

$$P_{n \geq n_i}(t) = \frac{2N_0}{t}\left(\frac{t}{2N_0 + t}\right)^{n_i} = \left(1 + \frac{t}{2N_0}\right)P_{n_i}(t) \tag{8}$$

Since all repeats are ultimately lost, $P_{n \geq n_i}(t) \to 0$ as $t \to \infty$, but goes through a maximum, for $N_0 \gg n_i$ at $t = 2N_0(n_i - 1)$. This is shown in Fig. 4.

Fig. 4 The probability of having at least n_i copies of gene i at time t, measured in units of N_0 crossovers.

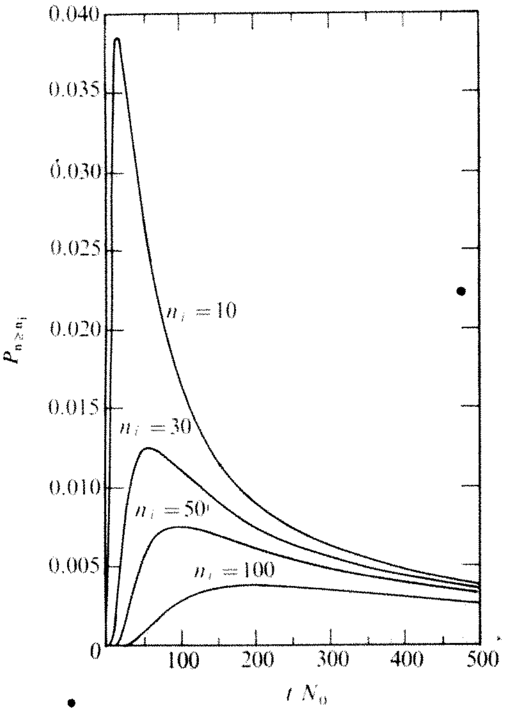

Table 1 Probability of generating multiple copies

n_i	t/N_0	P_{n_i}	$P_{n \geq n_i}$
1	0	1	1
>1	0	0	0
5	4	2.2×10^{-2}	6.6×10^{-2}
5	8	1.6×10^{-2}	8.2×10^{-2}
10	9	5.4×10^{-3}	3.0×10^{-2}
10	18	3.9×10^{-3}	3.9×10^{-2}
50	49	2.2×10^{-4}	5.5×10^{-3}
50	98	1.5×10^{-4}	7.4×10^{-3}
100	99	5.4×10^{-5}	2.7×10^{-3}
100	198	3.7×10^{-5}	3.7×10^{-3}
500	499	2.2×10^{-6}	5.4×10^{-4}
500	998	1.5×10^{-6}	7.4×10^{-4}

For some typical values of n_i, the number of repeats of the ith type, the probabilities $P_{n_i}(t)$ and $P_{n \geq n_i}(t)$ of finding exactly n_i copies and at least n_i copies, respectively, are given for $t = N_0(n_i - 1)$ and $t = 2N_0(n_i - 1)$. At these two times $P_{n_i}(t)$ and $P_{n \geq n_i}(t)$ attain their maximum values. In computing $P_{n \geq n_i}(t)$ we have assumed $N_0 \gg n_i$.

The probability of generating multiple copies of one particular gene by repeated unequal crossovers is surprisingly large, as illustrated in Table 1. Thus for $N_0 \gg 50$ in one out of every 135 organisms one gene would be replicated at least 50 times by unequal crossing over after $98N_0$ crossover events.

Gene fixation

Monte-Carlo simulations[27,29] have shown that after a large number of crossovers one gene tends to expand at the expense of the other genes in the multigene family. When a given gene comprises a large fraction of the family, its probability of subsequent loss is small, and one says that the gene has been 'fixed'. One can estimate the gene fixation time in two ways: let $M_e(t)$ be the mean number of extinct genes at time t. Because $P_0(t)$ is the fraction of genes that are extinct,

$$M_e(t) = N_0 P_0(t) = \frac{N_0 t}{2N_0 + t} \tag{9}$$

If

$$M_e(t) = N_0 - 1 \tag{10}$$

then the expected number of remaining genes is one. Combining equations (9) and (10) one finds that the expected fixation time, T_{bd}, determined by a birth–death process is

$$T_{bd} = 2N_0(N_0 - 1) \tag{11}$$

We have also computed the probability of one out of the original N_0 genes becoming fixed by time t, the probability of ultimate fixation, and show that the mean time to fixation in this birth and death model is precisely that given by equation (11). Our reasoning is as follows.

In the birth and death model we considered N_0 genes, each initially present in a single copy. The probability, $P_0(t)$, for any one of these genes to be extinct at time t was given by equation (5a). The

The coefficients $\lambda_{n_i}(t)$ and $\mu_{n_i}(t)$ can be identified as follows. As crossovers occur the number and order of genes on the chromosome may change. If there is an equal *a priori* probability of each repeat being influenced by crossover (that is duplicated or eliminated), then the probability of a particular gene, say gene i, being influenced by a crossover at time t is $n_i/N(t)$, that is, its fractional occurrence. Further we shall assume that the probability that a gene influenced by a crossover is duplicated equals p and the probability of its being eliminated is $(1-p)$. (In the absence of any selective force one would expect $p=1/2$.) Hence, measuring time by the crossover rate (so that one crossover is expected per unit time),

$$\lambda_{n_i}(t) = P\frac{n_i}{N(t)} \tag{3a}$$

$$\mu_{n_i}(t) = (1-p)\frac{n_i}{N(t)} \tag{3b}$$

Notice that

$$N(t) = \sum_{i=1}^{I} n_i(t)$$

is a random variable. With the birth and death parameters given in equation (3), the probability of having n_i copies of gene i will depend on the number of copies of all the other genes. To proceed we shall replace $N(t)$ by its mean value, which for $p=1/2$ is N_0. Thus we are approximating the birth and death rates λ and μ by their mean values. For other values of p, the mean value of $N(t)$ can be determined by considering a non-symmetrical random walk beginning at N_0 with an absorbing boundary at zero. In either event there is a finite probability for the loss of all the genes in the family; for $p \leq 1/2$ the ultimate loss is certain, while for $p > 1/2$ the extinction probability is

$$\left(\frac{1-p}{p}\right)^{N_0}$$

(ref. 38). When $p<1/2$ the expected lifetime of the family, measured in crossover events, is $N_0(1-2p)^{-1}$ (ref. 38). For $p=1/2$ the expected lifetime is infinite, while for $p>1/2$ the genes in the family may never be eliminated[38].

Under the assumptions $p=1/2$ and $N(t)=N_0$,

$$\lambda_{n_i} = \frac{n_i}{2N_0} = \mu_{n_i}, \qquad n_i = 0,1,\ldots N_0 \tag{4}$$

and equations (1) with initial conditions (2) reduce to the classical linear birth–death problem. The explicit solution, which may be found in Feller[38], is

$$P_0(t) = \frac{t}{t+2N_0} \tag{5a}$$

$$P_{n_i}(t) = \frac{(t/2N_0)^{n_i-1}}{(1+t/2N_0)^{n_i+1}}, \qquad n_i \geq 1 \tag{5b}$$

Observe that as $t \to \infty$, $P_0 \to 1$ and $P_{n_i}(t) \to 0$, and hence all genes in the family will ultimately be lost. It is easy to verify that

$$\sum_{n_i=0}^{\infty} P_{n_i}(t) = 1$$

that the mean value of n_i,

$$M_1(t) = \sum_{n_i=0}^{\infty} n_i P_{n_i}(t) = M_1(0) = 1$$

for all finite t, and that the variance $M_2(t) = t/N_0 + 1$. Hence for all finite times each of the original N_0 genes has a mean occurrence of one and a variance that increases linearly with time.

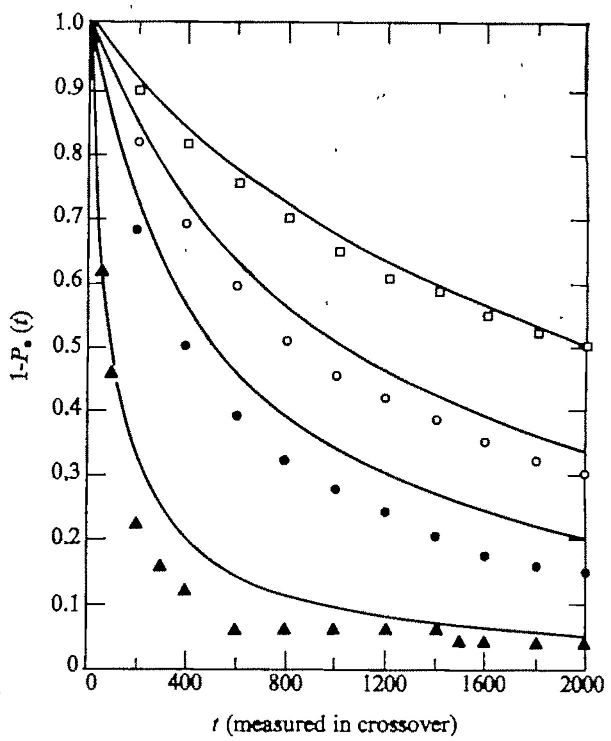

Fig. 2 Comparison of the predictions of the linear birth–death model (solid lines) with the Monte-Carlo simulations of Black and Gibson[29] (data points) The effect of the number of unequal crossovers and the size of the initial gene set on the rate of gene fixation. ▲, $N_0=50$; ●, $N_0=250$, ○, $N_0=500$; □, $N_0=1{,}000$

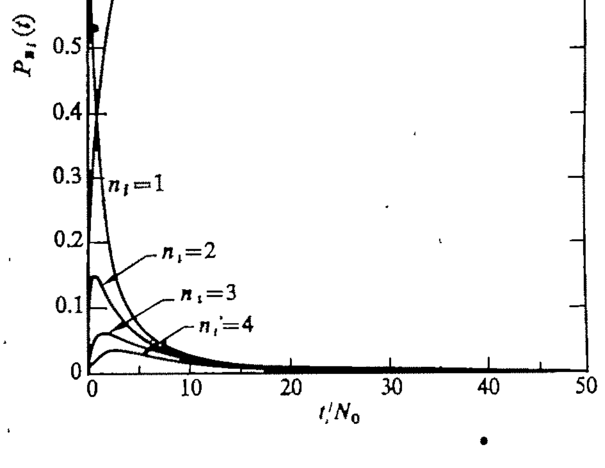
Even though the probability of any repeat being lost approaches one as $t \to \infty$, not all repeats will be lost in finite time, and in fact, one repeat will become fixed. One can understand this behaviour as follows: at $t=0$ there is one copy of each repeat At the first

Fig. 3 The probability of having n_i copies of gene i at time t, measured in units of N_0 crossovers for n_i between 0 and 4.



proven useful in the elucidation of a possible mechanism of gene magnification and reduction[2,13]. Restriction enzyme analysis and nucleic acid hybridisation have shown that about 50% of the DNA in the human Y chromosome is a simple tandemly repeated DNA (ref. 14).

It has been suggested[1,15] that sets of duplicated genes form multigene families, that is, are a group of nucleotide sequences or genes that exhibit the properties of multiplicity, close linkage, sequence homology and related or overlapping phenotypic functions. In particular, it has been argued that the genes that code for the variable regions of antibody molecules, V_λ, V_κ, and V_H, form three unlinked multigene families[1,15–18].

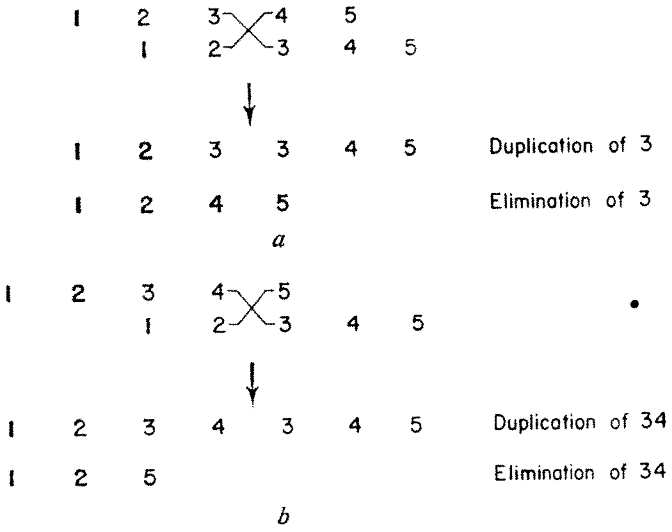


Fig. 1 Unequal crossing over between tandem sets of homologous genes and the products of the events. *a*, Mispairing by one gene; *b*, mispairing by two genes.

Genetic mechanisms need to be found which can not only generate repetitive gene sequences, but also explain the evolution of multigene families. Although the simplest hypothesis is to assume that the repeats in a multigene family evolve independently, there is evidence to the contrary. The genes within a multigene family can be maintained virtually identical within a species, and yet show divergence between species. This is the case with the spacer portions of the rRNA genes and the species-specific residues found in the conserved portion of the antibody V region that distinguish most immunoglobulins of one species from those of a second[19,20]. This unusual evolutionary property of multigene families termed coincidental evolution[1], species-specific evolution[19], horizontal evolution[21] and co-evolution[22], could be explained by parallel evolution, a gene correction process such as Callan's master slave hypothesis[23] or Gally and Edelman's democratic gene conversion theory[22], or, alternatively, a process of repeated duplication of some genes in a family and a loss of others[1,19]. Here we shall not discuss which of these proposals is most likely (for such discussion see refs 1 and 22), but we wish to point out that Tartof[2,13,24] has evidence supporting the hypothesis that unequal mitotic sister chromatid exchange is responsible for the magnification and reduction of rDNA in *D. melanogaster*, and that some proponents of the germ line theory of antibody diversity have suggested unequal crossing over as a mechanism of formation for species-specific V region subgroups[19,25–29]. Unequal crossing over has also been invoked to explain the origin of abnormal haemoglobulins such as haemoglobulin Lepore[30] and haemoglobulin Gun Hill[31,32], the variations in the length of the α chain of human haptoglobin[33], and the existence of the human γ-globulin hybrid γG3–γG1[34]. Southern[35] suggested that unequal crossing over might also explain the long-range periodicities found in mouse satellite DNA.

Smith[27,28], Black and Gibson[29], and Tartof[24] have used Monte-Carlo computer simulations to study the evolution of multigene systems through unequal crossing over. They have found that after large numbers of crossovers, one gene in the multigene family tends to become fixed while all other genes are lost asymptotically.

Monte-Carlo simulations can only deal with limited numbers of genes. Thus there is no way to be certain that results obtained on multigene families with say 10^3 repeats hold for simple-sequence families which may contain as many as 10^7 repeats of a single nucleotide sequence. If unequal crossing over is to be a credible theory for the evolution of multigene families, large families need to be studied. Here we develop a simple mathematical model of sister chromatid crossing over which yields predictions consistent with the Monte-Carlo simulations and which allows the computation of fixation times for a family of any size.

Crossing over can occur either at meisosis or mitosis[36]. Sister-chromatid exchanges have been observed to occur at frequencies of the order of 0.2 per chromosome per mitosis[37]. During unequal, intrachromosomal crossing over, sister chromatids carrying closely linked homologous genes mispair, crossover and produce two new sister chromatids, one containing a greater and the other a lesser number of gene repeats (Fig. 1). A mispairing by one position before the crossover yields a duplication of a single gene in one chromatid and the elimination of the same gene in the other chromatid, while a mispairing by k positions leads to the duplication and elimination of k genes. Thus, in so far as the state of the genome is determined by the number of copies of each gene and does not depend on gene order, any state attained by unequal crossing over can be realised by a sequence of unequal crossover events where the mispairing is by one repeat.

Mathematical model

Assume that at time $t = 0$ there are N_0 adjacent homologous DNA sequences which represent a multigene family. These sequences need not be identical, only similar enough to allow mispairing. We also assume that of the N_0 sequences I are distinct sequences ($I \leq N_0$), called "genes". These distinct sequences need not represent a classical gene but rather may represent a repeat unit containing multiple genes as in the case of *Xenopus* rDNA. We shall follow one of these I genes, say gene i, through a sequence of crossover events and determine the probability, $P_{n_i}(t)$, of there being n_i copies of this gene at some later time t, We assume that at $t = 0$ each gene, including gene i, is present in a single copy so $I = N_0$. For $t \neq 0$, the total number of homologous sequences, $N(t)$, is a random variable which need not be equal to N_0. Restricting our attention to mispairings by one repeat at any crossover events and determine the probability, $P_{n_i}(t)$, of there being n_i copies of this gene at some later time t. We assume that at one. If the probabilities of these events per unit time are $[1 - \lambda_{n}(t) - \mu_{n_i}(t)]$, $\lambda_{n_i}(t)$ respectively, a birth-death model[38] yields the following equations:

$$\frac{dP_{n_i}(t)}{dt} = -[\lambda_{n_i}(t) + \mu_{n_i}(t)]P_{n_i}(t) + \lambda_{n_i-1}(t)P_{n_i-1}(t) + $$

$$+ \mu_{n_i+1}(t)P_{n_i+1}(t),$$

$$n_i \geq 1, \qquad i = 1,2,\ldots N_0 \qquad (1a)$$

$$\frac{dP_0(t)}{dt} = -\lambda_0(t)P_0(t) + \mu_1(t)P_1(t),$$

$$n_i = 0, \quad i = 1,2,\ldots N_0 \qquad (1b)$$

with the initial conditions

$$P_{n_i}(0) = \begin{cases} 1 \text{ for } n_i = 1 \\ 0 \text{ for } n_i \neq 1 \end{cases}, i = 1,2,\ldots N_0 \qquad (2)$$

cells expressing a single Ig may produce one new mutant in the combining site every generation—say 12 h. A population of 10^8 such cells (an average *Nature* reader has 10^{12} lymphoid cells) could thus generate 200 mutant genes per day. This number compares with current estimates of the total number of germ line antibody genes.

In summary, stable, spontaneous, somatic mutations have been detected in antibody genes in the absence of antigen or other avoidable selective pressure. The observed mutations have been apparently non-random. The mutation rate may be high enough to generate the diversity required from the germ line genes. Although our results do not directly implicate somatic mutation as a mechanism for antibody diversification *in vivo*, it seems likely that somatic mutation, coupled with antigen selection of new antibody combining sites, has an important biological role.

Mathematical models for the evolution of multigene families by unequal crossing over

Alan S. Perelson & George I. Bell

Theoretical Division, University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico 87545

Mathematical models of homologous but unequal crossing-over between sister chromatids are presented. For mispairing by one repeat, the evolution of a multigene family by unequal crossing over can be represented by a linear birth–death process. The fixation rate of one repeat in a multigene family is estimated. For mispairing by more than one repeat, some approximate results are obtained.

EVIDENCE obtained during the past decade, reviewed in refs 1 and 2, has suggested that the eukaryotic genome contains multiple copies of certain nucleotide sequences, including genes. For example, satellite DNA isolated from *Drosophila virilis* contains about 10^7 copies of a heptanucleotide repeat known as satellite sequence I. Each cell also contains more than 10^6 copies of satellite sequences II and III, heptanucleotide repeats which could be derived from sequence I by single base substitutions. The gene coding for 28S and 18S ribosomal RNA (rRNA) in various eukaryotes has been found to be randomly repeated[2]. In the amphibian *Xenopus laevis* about 450 repeating units are clustered at the nucleolar organiser. Each unit has three major regions: 18S, 28S and spacer[3–5]. The spacer regions, which are not transcribed[6], are composed of a series of small tandem homology units. The number of these homology units differs from spacer to spacer and hence the spacers are heterogeneous in length[8,9]. Except for the spacer regions the 450 ribosomal units of *X. laevis* are identical to one another within the accuracy of DNA–DNA hybridisation techniques[4,7,10]. Comparison of the ribosomal repeats of *X. laevis* with its sister species *X. mulleri* shows that the 18S and 28S genes of the two species are indistinguishable, but the spacer regions differ widely in nucleotide sequence[4]. In *Drosophila melanogaster* tandemly repeated genes coding for rRNA (rDNA) are also clustered at the nucleolar organiser[11,12]. There is one nucleolar organiser on each X and Y chromosome. A mutant known as *bobbed*[12] has been isolated that is partially deficient in rDNA genes, and hence, has mutations at the mouse γ1 structural gene locus. They originate from four different mutation events (Table 1). Two of these seem to be point mutations—IF1 (a nonsense) and IF4 (a mis-sense). IF3 is a frameshift mutation resulting from a two-base deletion. The large deletion of IF2 may be due to a translocation or a mitotic recombination. All these processes have been well characterised in bacteria and lower eukaryotes. The studies described above show that they can take place in mammalian somatic cells. A statistical analysis of their relative frequencies is obviously premature. More examples may give some indication as to whether the greater complexity of the mammalian genome is associated with an alteration in the relative frequencies of the mutation events. In general, studies on mutations of somatic cells have involved mutagens. An important question is whether these agents merely increase mutation rates, or cause mutations that rarely (or never) occur spontaneously, or both. The studies above, although very restricted, provide a background on the more neglected area of spontaneous mutation. The procedures described above can equally be used to characterise the structural alterations induced by mutagens, particularly carcinogens.

Table 1 Structural mutants of MOPC 21 (P3) mouse myeloma. The molecular weights are calculated from their sequences allowing 2000 daltons for carbohydrate

	Wild type	Mutants			
	MOPC 21	IF1	IF2	IF3	IF4
Molecular weight	50,800	41,300	40,900	40,700	50,800
H-chain defect		Deletion of C_H3 (residues 358–440)	Deletion of C_H1 (residues 121–214)	Altered sequence of residues 341–354 followed by deletion of C_H3	Asparagine to aspartic acid (residue 415)
Sialic acid	−	+	−	−	−
Binding to F_c-receptor[48]	+	−	+	−	N.D.
H-chain mRNA size	17S	17S	16S	17S	17S
Proposed genetic mechanism		Point mutation ('nonsense')	Intracistronic deletion	Frameshift (−2) Premature 'ochre' termination	A to G transition ('mis-sense')

N.D. not determined.

Somatic mutation and antibody diversity

There were about 300 generations between the isolation of the P3 clone and the detection of mutants. Since five mutants were isolated from 7,000 subclones, the electrophoretic mutation rate of H-chain genes can be calculated, using the Catcheside approximation[39] as 3.3×10^{-6} per cell per generation. This mutation rate is higher than those reported for spontaneous auxotrophic mutants of Chinese hamster ovary cells in culture[6] or for spontaneous variations in other mammalian cell systems[12,17], which are less than 10^{-8} per cell per generation.

From the H-chain sequence and the genetic code, we have calculated that 23% of all theoretically possible point mutations (two out of four in our case) will lead to a charge change[29]. The corrected mutation rate (to include electrophoretically silent mutations) approaches 10^{-5} per cell per generation. This calculated rate must be a conservative estimate for several reasons. Certain mutations might lead to distortions in the protein structure causing problems of solubility and resulting in either a rapid catabolism[40] of the protein, or in cell death. In others, the mutant polypeptide chain might be too small to be detected by our methods. The low levels of mutant polypeptide chain might be too small to be detected by our methods. The low levels of mutant proteins found in the sera of tumour-bearing mice may be a result of any of these processes of selection.

The striking similarity between IF2 Ig and the human heavy-chain disease proteins[41] has been stressed before[22] and may be related to the mechanism of integration of V and C genes. The point mutation in IF4 also occurs in an interesting residue. Variants of human kappa and lambda chains have been located in a homologous region. Residue 415 of MOPC 21 H chain, the O_z marker of lambda chains[26], and the Inv marker of kappa chains[26] are, respectively, four, four and three residues before the second pseudosubunit half cystine. The mutations in IF1, IF2 and IF3 are all outside the pseudosubunit disulphide loops although more residues (247 residues) are within than outside (193 residues) the pseudosubunit disulphide loops (Fig. 4). This apparent bias in favour of mutations outside the loops could be the result of strong selective pressure at the protein level against mutations (or deletions) within the disulphide loops. In addition, normal mutation rates may be dependent on the DNA sequence[42,43] and there might be mutational 'hot spots'. This is particularly applicable to the deletion of IF2 which starts at the V–C junction and ends at the residue repeatedly involved in deletions[41]. Selection might also occur at the mRNA level, against mutants with less than optimum base-pairing arrangements. Such mutants could lead to mRNA instability resulting in the loss rather than the alteration of chains. The possibility that experimental immunoglobulin mutations may occur non-randomly along the chain has implications for the antibody diversity problem.

The functions of the immune system include the recognition of, and response to, an apparently limitless array of antigens. Variability in each Ig class or subclass is confined to the V regions, especially in the 50–70 residues that form the antigen-binding sites[44] in the V_H–V_L domain: the hypervariable residues. Recent results on quantification of the number of germ line genes by molecular hybridisation methods indicate that somatic mutation of antibody genes has a role in the diversification of Ig binding site sequences (reviewed in ref. 45). In the mutations reported here the V regions have not been involved. This may be due to the small number of mutants studied but it may be also that our cell line, which is already committed to Ig production, behaves differently from antigen-sensitive virgin cells. Cunningham and coworkers[46] have suggested that most combining site diversity occurs in a clone of cells after, and as a result of, antigen contact. If this is so, higher mutability should be expected on antigenic stimulation. However, the stability of a clone of antibody-producing cells *in vivo*[47] does not support such a view. Even so it is possible that uncommitted cells have a higher mutation frequency in their hypervariable region than more mature cells. We have suggested that some of the germ line genes include DNA sequences signalling higher mutation rates[50]. This advantage may decline as mutants develop in the direction of more stable configurations.

The conservative mutation rate calculated here for the whole IgG is about 10^{-5} per cell per generation. Since hypervariable regions represent only 10% of the total molecule a mutation rate of 10^{-6} per cell per generation will affect the combining site. This means that even in committed cells a clone containing 10^6

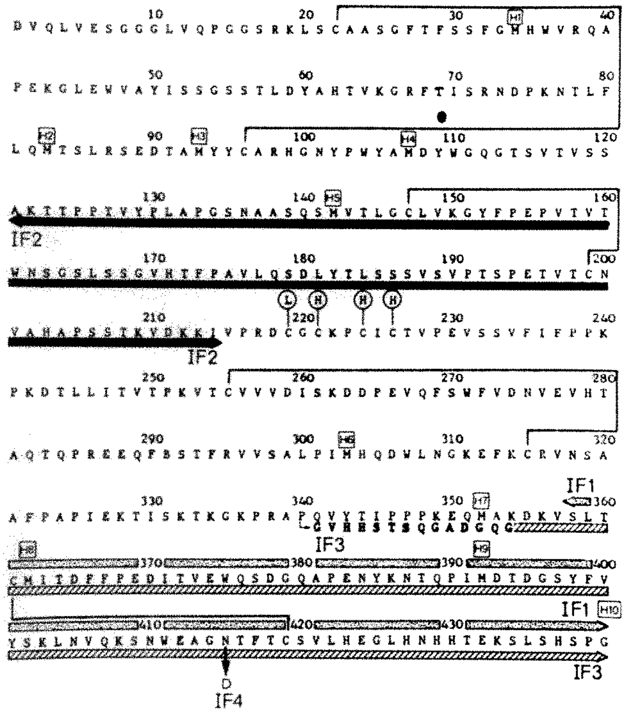

Fig. 4 The sequence of MOPC 21 H chain and of its mutants. The horizontal arrows indicate the extent of the deletion in each mutant. For IF3, an altered sequence continues for 14 residues beyond Pro-340 (see Fig. 5), and for IF4, Asn-415 is replaced by an Asp. H1, H2, and so on indicate the C-terminal residue of the respective CNBr fragments of MOPC 21 H chain.

29, 32) was the electrophoretic mobility (*p*H 6.5) of the ^{14}C-carboxymethylcysteinyl peptide H10T3 (ref. 34), residues 409–433 (Fig. 3) Thermolysin digestion of this peptide showed that while in wild-type Asx-415 was present in the neutral peptide Ala-Gly-Asn-Thr, in IF4 H chain it was in the acidic peptide Ala-Gly-Asp-Thr. The difference in structure between wild-type and mutant IF4 is therefore an asparagine–aspartate interchange at residue 415. (Pulse-labelled (15-, 30- and 60-min pulses) intracellular wild-type and IF4 immunoglobulins showed the same charge difference as the two proteins isolated from sera, indicating that the difference is not a result of deamidation. Further evidence on this point was obtained by fingerprint analysis of the H-chain mRNA from mutant cells. An oligonucleotide obtained by digestion with T$_1$-ribonuclease (h6, Fig. 5), which was proposed to code for residues 414–419, had been previously isolated from ^{32}P-H-chain mRNA (ref. 31). The Asn → Asp interchange at 415 implies an A → G transition and therefore a split in oligonucleotide h6 at the new G residue. Fingerprints of IF4 ^{32}P H-chain mRNA showed that h6 was not present in the mutant. Unfortunately the predicted alternative oligonucleotide could not be positively identified. It is smaller than the wild type form and likely to be obscured by other oligonucleotides. The evidence indicates that the Asn–Asp interchange is the result of a point mutation.

Significance of the mutations

The mutations described above are not due to post-translational modifications. This was established by translation *in vitro* and structural studies of isolated mRNA. The possibilities that the mutant proteins are all due to post-transcriptional modifications of RNA or derived from genes silent in wild-type cells but expressed in the mutants, are not formally excluded but are most unlikely for several reasons. All the mutations are consistent with simple genetic events (Table 1) and no other primary sequence differences were detected. Each mutant represents a unique sequence, not observed in other myeloma proteins. Therefore, at least four, but probably more, such silent genes would have to be postulated. In addition, immunoglobulin V and C genes require an integration process for the expression of the mRNA[26,35]. This integration occurs during differentiation of stem cells into plasma cells[36,37]. The expression of a silent C gene would require a retranslocation of the V gene, since the V region of the mutants is the same as that of the wild type. Translocation of V genes onto new C genes in somatic cells *in vivo* gives rise to the expression of other known H-chain classes[26]. This type of translocation has not been observed with plasma cells in culture. Attempts to detect them in established cell lines have been unsuccessful[32]. In other cases, however, it has been suggested that a modified C gene, with characteristics of another subclass, was detected in chemically-induced mutant cells as a result of deletion or unequal crossing over[38].

We conclude that IF1, IF2, IF3 and IF4 represent spontaneous

Fig. 5 The sequence of two stretches of wild-type heavy chain and of mutants. *a*, Sequence of the wild-type[22] and IF3 H-chain can be read from a single mRNA sequence assuming a deletion of two bases, giving rise to a frameshift. Alternative positions of the deletion are indicated. *b*, Alteration of the point mutant IF4. T$_1$ oligonucleotide sequences taken from ref. 31.

Thus, the 94 residues from 121 to 214 of the wild-type chain were missing from the sequence of this mutant and a new bond corresponding to Ser$_{120}$-Val$_{215}$ was found. The amino acid analysis of all CNBr fragments of IF2 H chain, the peptide maps and the amino acid compositions of the tryptic peptides[29], were consistent with the proposed internal deletion of 94 amino acid residues (Fig. 4).

The mRNA prepared from this mutant can be translated in cell-free systems to give a mutant heavy chain. Unlike IF1, the mRNA of IF2 does not comigrate in sucrose gradient sedimentation with the wild-type H-chain mRNA, but is significantly smaller. The decrease in size, from 17S to 16S, is consistent with an internal deletion of about 300 bases[31]. Since the mRNA is itself shorter, we conclude that the deletion originates in a deletion at the DNA level.

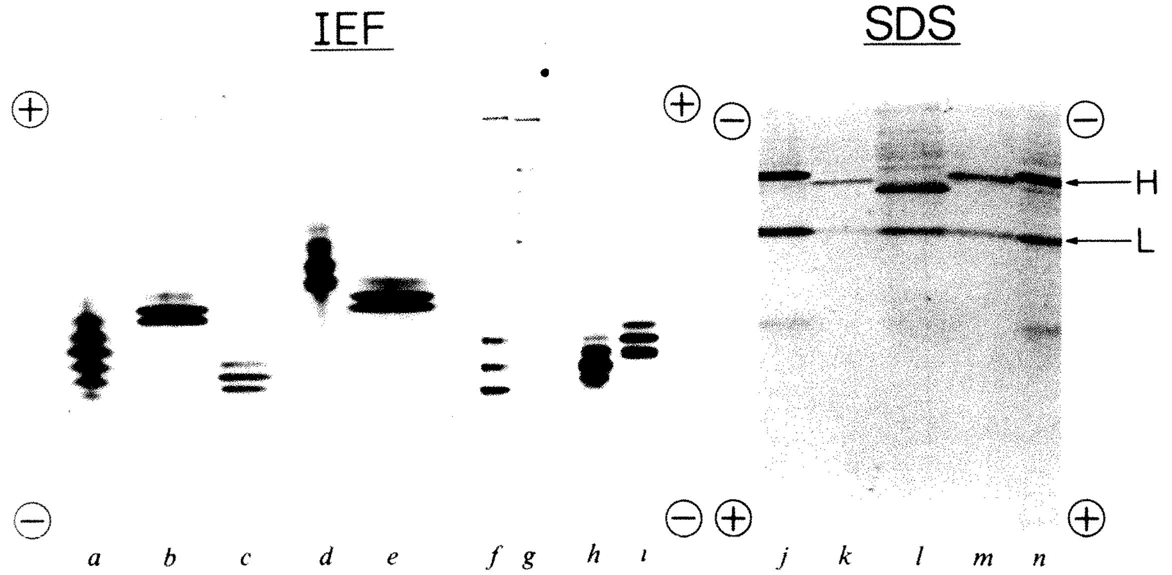

Fig. 3 Comparison of wild-type and mutant immunoglobulins (or Ig chains) by isoelectric focusing[20] (IEF) (*a–i*) or SDS–polyacrylamide slab gel electrophoresis[49] in a 20% acrylamide 0.065% *bis*-acrylamide gel (*j–n*). Igs were reduced by boiling with 2-mercaptoethanol in 1% SDS before applying to the gel. Ig was prepared either by the incorporation of ^{14}C-lysine into secreted protein by cells in culture[20] (*f, g, j–n*), in which case proteins were visualised by autoradiography of the dried gel, or from the sera of tumour-bearing mice[25] (*a–e, h, i*). Typical yields of Ig ml^{-1} of mouse serum were: wild type, 10–20 mg; IFI, 1–2 mg; IF2, 2–4 mg; IF3, 0.7–1.5 mg; IF4, 4–6 mg. For isoelectric focusing the *p*H gradients were: 5-8.5 (*a-e*), 6-8 (*f, g*), or 5-8.5 in 6 M urea (*h, i*). (*b, e, f, n*), wild type; (*a, m*), IF1; (*c, k*), IF3; (*d, j*), IF4; (*g, l*), IF2; (*h*), wild-type H chain; (*i*), IF4 H chain. +, anode; −, cathode. H, L, indicate the position of unlabelled marker wild-type H and L chain.

A frameshift mutant

IF3 was more basic than the wild type (Fig. 2), and its *p*I was not altered by neuraminidase treatment. As in IF1 and IF2, its L chain comigrated with wild-type L chain in SDS–polyacrylamide gels. The H chain had a faster mobility than (Fig. 2) and a different amino acid composition from wild-type H chain[29]. The three C-terminal CNBr fragments of the wild type (H8, H9 and H10, Fig. 4) were not present in IF3 H chain. The six N-terminal CNBr fragments (H1-H6) were unaltered, as judged by their amino acid compositions, the electrophoretic mobilities of fragments H4 and H5, and fingerprints and amino acid compositions of the tryptic peptides of the larger fragments. A new CNBr fragment, IF3-H7′, was isolated[29]. It had approximately the same size as wild-type H7, but a different amino acid composition. This CNBr fragment had no homoserine and was presumably the C-terminal fragment of IF3 H chain. Tryptic peptides corresponding to residues 304-338 from wild type were present in IF3-H7′. Fingerprinting of a tryptic digest of performic acid-oxidised IF3 H chain showed a peptide, IF3H-T28, that was not present in fingerprints of wild-type H chain. This peptide was isolated in very good yield and had the sequence:

Ala-Pro-Gly-Val-His-His-Ser-Thr-Ser-Gln-Gly-Ala-Asp-Gly-Gln-Gly

It was concluded[32] that this peptide corresponds to residues 339 to the C terminus, as the terminal glycine does not represent a point of tryptic, pseudotryptic, or CNBr cleavage. This peptide, plus those isolated for residues 304–338, completely account for the amino acid composition of IF3-H7′. Thus, the sequence of IF3 H chain is identical to the wild type in the first 340 positions. The sequence of the C-terminal 14 residues is not found in wild type, other mutants, or any other immunoglobulins, but it can be related to the sequence of wild type by postulating a -2 frameshift mechanism (Fig. 5). This explanation fits with the published mRNA sequence data and allows a unique sequence of 55 bases to be deduced for wild-type H-chain mRNA. It predicts that UAA (‘ochre’) is the terminator codon in the mutant. This is supported by experiments[33] showing that when IF3 H-chain mRNA was supplemented with UAA-suppressor tRNA in a cell-free system, suppression was detectable, and a new product larger than mutant but smaller than wild-type H-chain was found. No difference in the size of the mRNA was detected by sucrose gradient centrifugation[31]. The mutant is therefore a frameshift mutant due to a deletion of two of the bases coding for Pro-Gln residues at positions 340–341 of the H chain.

A point mutant

IF4 Ig was more acidic than wild type (Fig. 3). The *p*I was not altered by neuraminidase. Isoelectric focusing of partially reduced and carboxymethylated chains showed that the difference was located in the H chain (Fig. 3). No differences were detected between wild-type and IF4 H-chains, by SDS–polyacrylamide gel electrophoresis or amino acid analysis.

The main product of limited peptic proteolysis of wild-type Ig is fragment (Fab′)$_2$[25], a four-chain molecule made up to two intact light chains and two Fd′ fragments (residues 1–232 of the H chain). The (Fab′)$_2$ fragments from wild type and IF4 had identical *p*I, as did the main CNBr fragment (residues 143–303) of the H chains. The only detectable abnormality of IF4 (refs

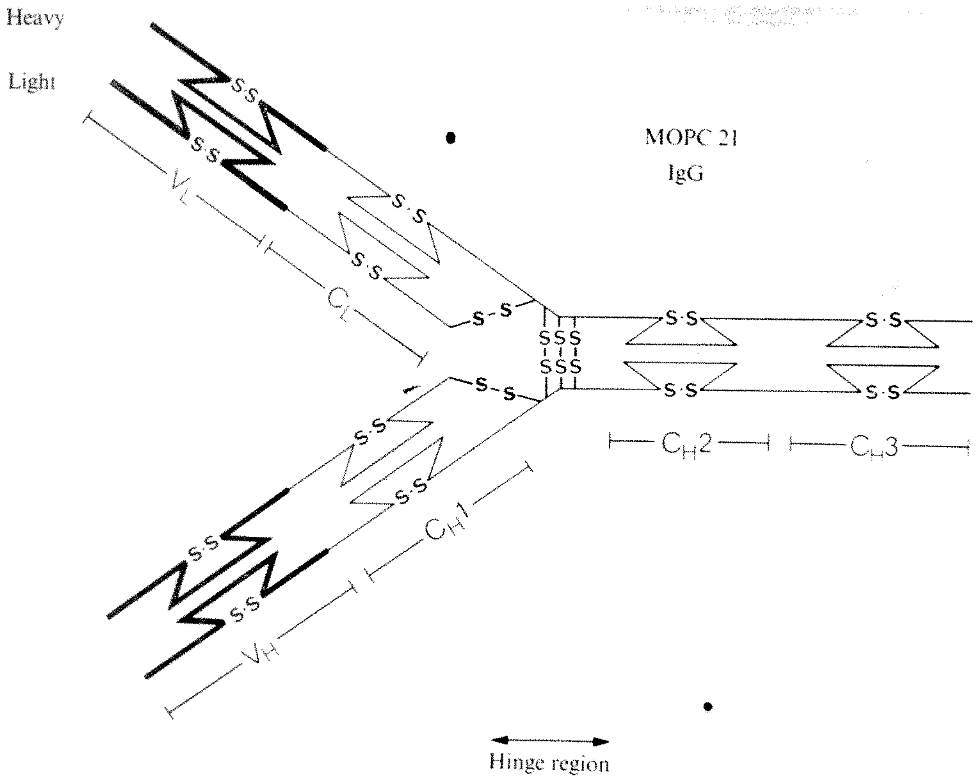

Fig. 1 Diagrammatic representation of the IgG molecule. The pseudosubunits are named and the antigen binding domain (V region) is marked with heavy lines.

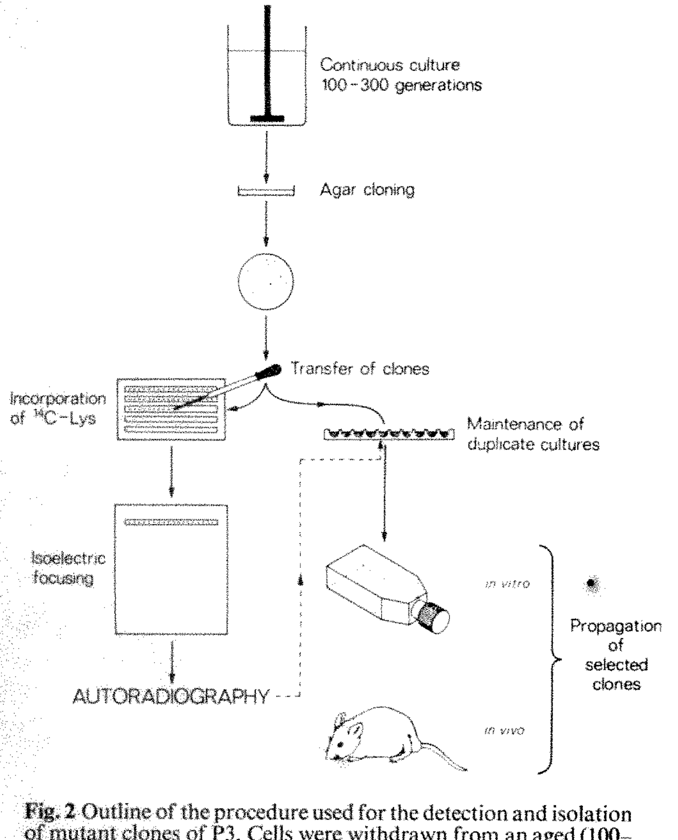

Fig. 2 Outline of the procedure used for the detection and isolation of mutant clones of P3. Cells were withdrawn from an aged (100–300 generations) spinner culture and subcloned in agar. When subclones were visible to the naked eye (12–14 d) they were transferred on to a layer of dialysis membrane on agar growth medium containing ^{14}C-lysine and incubated for 24 h. Replicas of sampled clones were maintained in microculture wells. After incubation the dialysis membrane containing the radiolabelled samples was applied on to thin slabs of polyacrylamide (4.5%) gels and isoelectric focusing was performed. The radioactive immunoglobulin bands were visualised by autoradiography. Further details have been published[20]. Clones whose Ig bands show an altered isoelectric point were recovered from the replicas in microculture wells, grown to mass in suspension, and inoculated into BALB/c mice, in which they grew as solid tumours.

radioactive peptides from peptic and tryptic digestions of labelled wild-type and IF1 H chains[28] showed that the marker peptides from the C_H3 pseudosubunit (see Fig. 1) were missing. Cyanogen bromide fragmentation of IF1 H chain confirmed these findings. The three CNBr fragments of C_H3 (H8, H9, H10) (Fig. 4) were missing. A new CNBr peptide with N-terminal alanine was found, corresponding to the sequence Ala-Lys-Asp-Lys-Val_{357} (ref. 29). Since this peptide had no homoserine, it was presumably the C-terminal fragment of IF1 H chain. The other CNBr fragments were identical to wild type fragments by amino acid analysis and peptide finger-printing techniques. No internal duplication of sequences was detected, so IF1H represents residues 1–357 of the wild-type sequence (Fig. 4), and is 83 residues shorter than the wild-type protein.

The mRNA from this mutant can be translated in cell-free systems. The translation product is smaller than the wild type, indicating that the mRNA itself is altered[31]. A comparison of the size of the mutant and wild-type H chain mRNA by sucrose gradient sedimentation showed that the protein deletion was not due to a corresponding deletion at the mRNA level. The mutation is therefore most probably due to a nonsense mutation in the codon of Ser-358 resulting in premature chain termination. The reason for the alteration in the carbohydrate composition remains unknown. It is possible that this is a secondary effect due to local changes in protein folding. This may lead to a new site for carbohydrate attachment or greater accessibility to sialic acid addition.

An internal deletion

IF2 IgG was more acidic than the wild type counterpart, and its heavy chain was smaller (Fig. 3). Neuraminidase treatment did not affect the *p*I (ref. 30). Fingerprint studies of ^{35}S-cystine and ^{14}C-lysine, ^{14}C-arginine labelled IF2 H chain showed that the C_H1 (see Fig. 1) peptides were missing and that the hinge region peptide was altered. CNBr digestion of IF2 H chain produced a new fragment, H56, in place of H5 and H6 (Fig. 3). A sequentator analysis of H56 gave the N terminal sequence:

Molecular analysis of spontaneous somatic mutants

Kayode Adetugbo*, César Milstein & David S. Secher†

Eukaryotic structural gene mutations occurring spontaneously in a mouse myeloma cell line offer the opportunity to study somatic mutation in animal cells at the molecular level. Studies on the myeloma protein and on mRNA have enabled us to characterise four such mutants representing four different mutation mechanisms. The results may have some bearing on the origin of antibody diversity.

THE nature and rate of mutation in somatic cells is of considerable interest in connection with a wide range of biological phenomena including carcinogenesis[1], immunology[2] and ageing[3]. Many cases of somatic mutations in animals are known and several have been extensively studied at the phenotypic level (for example mosaicism of fleece type[4]). In no case, however, has the phenotypic variation been unequivocally shown to be due to a mutation in a given structural gene. In some cases, for example certain haemoglobinopathies[5], non-inherited alterations of haemoglobin have been reported. But these could equally be new spontaneous mutants of the germ line cells. Studies of somatic variants in animals are limited by the death of the individual. For this reason most of the efforts to characterise somatic mutants in eukaryotes have been made on cells in culture. This was made possible by developments in cloning techniques[6] and a considerable number of examples of clonal variants have now been reported[7,8].

It was originally suggested[9,10] that variants in tissue culture were of epigenetic origin, that is heritable variations (as observed in differentiation) not involving alterations in DNA sequence. More recent reviewers, however[7,11], have concluded that many of the described variants are indeed genetic. But the localisation of these mutations to specific structural genes remains incomplete. The presence of altered proteins in variant clones provides preliminary evidence for structural gene mutations. Alterations in enzyme activity[12-14], immunoreactivity[13,15,16], temperature sensitivity[12,17-19] and electrophoretic properties[20] have been taken as evidence of structural gene mutations. Chemically-induced mutant cells with no hypoxanthine guanine phosphoribosyltransferase activity, for example, have been shown to contain material that cross reacts immunologically with the enzyme and is presumably inactive protein; this material comigrates with wild-type enzyme in SDS–polyacrylamide gels[13,15]. Hochman *et al.*[21] have pruified the regulatory subunit of cyclic AMP-dependent protein kinase in mutants of mouse lymphoma cells; the mutant protein has altered temperature sensitivity and enzymatic properties. Such mutants are presumably due to structural changes in the protein and may well be the result of mutations in the structural gene. But these methods of analysis do not exclude changes in post-translational modifications such as carbohydrate addition, phosphorylation, processing of precursor molecules, and so on. These often modify physicochemical and biological properties of protein molecules.

Amino acid sequence analysis of the altered proteins, to allow a more exhaustive characterisation of mutants, is hampered by the difficulty in obtaining enough material. This can be, at least partially, overcome by the use of radioactive tracer techniques. This approach was successfully used for the preliminary characterisation of structural mutants of immunoglobulin genes in myeloma cells in culture[16,22]. Further characterisation of such mutants, including complete amino acid sequence analysis, is possible. Preparation of large quantities of mutant protein is simple when the cells are grown as tumours in mice since the myeloma proteins accumulate in the serum.

Spontaneous structural gene mutants

The mouse plasmacytoma MOPC 21 is an experimentally-induced tumour which secretes an immunoglobulin (Ig) consisting of γ1 heavy chains and kappa light chains [IgG1(κ)] (ref. 23). Both chains have been fully sequenced and the arrangement of disulphide bridges elucidated[22,24,25]. The light (L) and heavy (H) chains are made up of pseudosubunits of ~ 110 residues, each containing a disulphide loop (Fig. 1. For further details of Ig structure and genetics see ref. 26). A line adapted to permanent growth in tissue culture has been derived and is known as P3 (ref. 27). This line has been repeatedly cloned and individual subclones have been screened for the presence of isoelectric focusing variants of the secreted immunoglobulin. The procedure (outlined in Fig. 2) allowed the analysis of a random sample of 7,000 subclones.* Five mutant clones, secreting immunoglobulins of altered isoelectric points were detected, but one was lost. Figure 2 shows the other four, which we named IF1, IF2, IF3 and IF4. Initial sequence studies were at the radioactive level with material prepared in tissue culture[28]. More conventional methods[29] required milligram quantities of material which was prepared by injecting the mutant cells into BALB/c mice. Tumours were generally obtained directly, but sometimes irradiated mice (400 rad) were used during the early passages. The yield of mutant proteins in the serum of the tumour-bearing animals was lower than in the wild type (Fig. 3).

A nonsense mutant

IF1 had a higher *p*I than the wild-type protein and its H chain a lower molecular weight than wild type by SDS–polyacrylamide gel electrophoresis (Fig. 3). Neuraminidase treatment, to remove specifically sialic acid, followed by isoelectric focusing, produced a further shift in IF1, but no effect on wild type[30]. Thus, in addition to primary sequence differences (see below), IF1 Ig had sialic acid, whereas wild-type Ig did not. A comparison of the

In an attempt to understand better the molecular nature of toxin synthesis, So *et al.* have recently cloned the genetic determinant of ST toxin (*J. Bact.* **128**, 463; 1976). Using the well established techniques of *in vitro* DNA recombinant research, they were able to clone a 5.7 megadalton *Eco*RI-derived DNA fragment determining toxin production in plasmid pSC101 which carries a tetracycline resistance marker, and in plasmid RSF2124 which is an ampicillin-resistant ColE1 derivative. This latter plasmid is present in 20–30 copies per cell and continues replication after chloramphenicol treatment of cells containing it, allowing isolation of large quantities of cloned DNA. Thus the tools are now available to investigate the properties of the toxin and its coding DNA sequence more thoroughly. The cloned sequence or a part thereof can be used as a 'probe' to detect rapidly the presence of ST toxin DNA and related sequences elsewhere. It should also now be possible to study transcription and translation of the cloned DNA, either in *E. coli* 'minicells' or *in vitro*.

This is the first published report of the cloning of a genetic determinant of bacterial pathogenicity, and it is interesting to note how these experiments conform to the various regulations and guidelines intended to control *in vitro* DNA recombinant research. In the USA, the NIH guidelines fairly explicitly categorise such experiments as requiring low containment (P2, EK1), since ST toxin is classified as of low pathogenicity. Such containment conditions at least would normally be used for handling the original toxin-producing strains. Experiments involving DNA of moderate pathogenicity, for example that isolated from *Vibrio cholerae*, would in addition require a disabled vector (P2, EK2), whereas DNA from organisms of high pathogenicity should not be cloned at present. In Britain, the situation is less clear, as experimental protocols and details of available facilities now have to be submitted for consideration by the Genetic Manipulation Advisory Group (GMAG), although the report of the working party on genetic manipulation indicates that cloning of DNA from "bacteria specifying toxins virulent to man" should only proceed with a disabled vector and under the highest physical containment (category IV), whereas cloning of "bacterial DNA non-pathogenic to man" may be carried out under minimal containment conditions.

Much then depends on whether ST toxin is considered virulent to man. It might be good practice for the newly constituted GMAG to consider and decide the categorisation for the So *et al.* experiments! The authors of the paper discuss the possible hazards, implications and benefits of their work. They point out that the ST-toxin determinant was found naturally in *E. coli* as part of a common type of conjugative plasmid which often also contains drug resistance genes. Tetracycline resistance and ampicillin resistance, which are present in the cloning vectors, are often present in toxigenic *E. coli* strains. Therefore no new combinations of drug resistance and toxin production had been produced by the cloning experiments. In addition, the authors were aware that ST toxin production in *E. coli* K12 (the strain used in the laboratory) was unable to cause disease symptoms. Even production of both toxins is not by itself sufficient for a strain to be pathogenic. A host of other, as yet poorly-defined characteristics are required: some concern the properties of the bacterial cell surface and at least one, the K antigen, is plasmid encoded.

Taking this into account So *et al.* felt that the new toxin-producing plasmids, if properly contained, present less of a hazard than the original plasmid in its original strain. It is now known than many drug-resistance genes are readily transposable from replicon to replicon, allowing new combinations of plasmid-borne drug resistance to arise at high frequency. It seems likely that many other plasmid determinants including toxin production will also turn out to be transposable; therefore it looks as though any gene combination that can be made from *E. coli* plasmids by the techniques of *in vitro* DNA recombinant research can occur fairly readily in nature, and if suitable conditions (those provided by the indiscriminate use of antibiotics for example) are available, then hazardous combinations of drug resistance and genes for pathogenicity can be selected and may become a serious problem for the medical and veterinary profession.

Williams Smith has also shown (*J. gen. Microbiol.* **47**, 153; 1967; *J. gen. Microbiol.* **83**, 95; 1974) that production of α-haemolysin and a toxin known as Vir is plasmid specified and associated with pathogenicity of invasive *Escherichia coli* strains. Similarly the presence of plasmids determining colicin V production seems to enhance pathogenicity, apparently by increasing survival of bacteria in blood and the peritoneum. If this effect is the result of colicin V production, then one has the intriguing example of a colicin protein, which is normally only considered to be active in killing *E. coli*, being involved in pathogenicity.

Studies of bacterial toxins are of interest not only to the bacteriologist. Both cholera and diphtheria toxin have already proved invaluable tools to molecular biologists studying eukaryotes because of their highly specific hormone-like interactions both with the cell surface and with their targets within the cell. Cholera toxin has been used as a tool to investigate membrane receptors, as a model for the study of hormone action and as a cyclic AMP probe (for example Finkelstein, *Microbiology-1975*, American Society for Microbiology, **237**, 1975). Similarly diphtheria toxin has been used to block translation of mRNA into protein by enzymatically depleting elongation factor 2 (EF-2) in eukaryote cells. There is also speculative material for the molecular evolutionist: are these toxins of eukaryote origin or can their interactions with the eukaryotic cell throw light on the relationships between eukaryotes and prokaryotes? □

Erratum

In the article 'Diamond platelets are interstitial carbon' (*News and Views* **265**, 208; 1976) line 5, paragraph 3 should read ". . . concentrations up to 1%" and not "up to 12%", and line 13, paragraph 5 (page 209) should read "No more than 3%" and not "No more than 5%".

A hundred years ago

THE electric light is becoming common in Paris in connection with works that have to be carried on during the night. A large lamp fed by a six-horse power has been established in the Avenue de l'Opéra, and others are employed in the Trocadero in connection with the building of the Exhibition Palace. The gramme machine and screw regulator are employed.

THE INTRA-MERCURIAL PLANET.—In M. Leverrier's last communication to the Paris Academy on the planet assumed to exist within the orbit of Mercury, it was mentioned that, with the elements adopted, or very similar ones, a solar conjunction would occur on March 22, and a transit over the sun's disc was possible, though uncertain. A close examination of the disc is therefore to be recommended on March 22 and 23, and there is reason to believe that observers in widely-differing longitudes are prepared to undertake it. If no transit should then occur, eight or nine years may elapse before one is possible at the spring node.

Regulating gene expression in differentiation

from Carol K. Klukas

CONSIDERING the number of different cell types which exist in any mature eukaryotic organism, and the number of individual differentiation events which must have occurred in precisely ordered sequence in the course of its development one is left in no doubt that the system which so precisely controls genome expression in eukaryotes must be incredibly complex.

Research into many different aspects of the control system is currently in progress in many laboratories, and a recent paper from Strom and Dorfman (*Proc. natn. Acad. Sci. U.S.A.* **73,** 3428; 1976) offers new evidence in support of the theory first put forward by Britten and Davidson, that the intermediate repetitive sequences in the genome may have a crucial role in regulating gene expression.

An early theory of the control of eukaryotic gene expression which proposed that appropriate structural genes are singled out and amplified during differentiation has generally proved to be untrue. Gene titration experiments have indicated only one or at most a few copies of any one structural gene, even in cell types where the protein that the gene specifies makes up a large proportion of the total protein synthesised. Research has therefore concentrated on the investigation of possible transcriptional controls, such as the interaction of non-histone proteins and hormones with chromatin, and the sequence organisation of the DNA itself. In 1969 Britten and Davidson (*Science* **165,** 349; 1969) first suggested how, theoretically, intermediate repetitive sequences might control gene expression, and more recently (Davidson *et al. Cell* **4,** 217; 1975) they have found that 80–100% of the mRNA molecules present in sea urchin embryos are transcribed from single copy DNA sequences which are adjacent to interspersed repetitive sequences in the genome. This finding does indeed suggest the regulatory importance of these sequences.
